No satisfactory history of early infection could be developed, although it was found that at the age of 9 years the patient had had persistent aching of his forearms.

Four months after drainage of the hip the patient was active without weight bearing and in excellent condition clinically. FRANK E. BREIDENBECK, M.D.

Eosinophilic Granuloma. WILLIAM J. BAKER, JOHN D. HOOVER, EUGEN WIMMER, and KEVIN H. BEITZ. *N England J M* 1948, 73, 686.

A review of the literature since 1940, when eosinophilic granuloma was simultaneously described by Lichtenstein and Jaffe and by Otani and Ehrlich,

includes about 45 case reports. Eighty per cent of the patients were children the oldest patients were a man of 35 years and a woman of 50 years.

Characteristic of the disease is its increased frequency in males and its occurrence oftenest in ribs or skull. Lesions may be single or multiple but the bones of the hands and feet are spared.

X-ray findings are characteristically punched-out areas which may erode the cortex and produce pathologic fractures. Laboratory findings are usually not abnormal.

Biopsy of the granuloma shows soft, yellow tissue with some hemorrhagic, and some necrotic areas. Sheets of eosinophils are found along with phagocytic mononuclear and multinuclear histiocytes.

The case reported is that of a 30-year-old man in whom roentgenography revealed a rapid progression of the lesion. The patient had constant soreness in the right anterolateral chest wall for 6 weeks before being seen. The roentgenogram showed a small cystic area in the seventh rib, which in 4 more weeks was markedly increased in size, with cortical erosion. At 8 weeks from the time of the original roentgenogram a wide area of destruction localized to the seventh rib was visualized. A pathologic fracture traversed the area.

Partial resection of the affected rib showed typical gross and microscopic eosinophilic granuloma. A rapid and uneventful convalescence ensued. Check up in 6 months showed healing at the site of biopsy and all physical findings were normal.

FRANK E. BREIDENBECK, M.D.

Congenital Pseudarthrosis. Follow-Up Study after Massive Bone Grafting. HAROLD B. BOTT and KERMIT W. FOX. *J Bone Surg* 1948, 30-A: 74.

A report was made of 7 cases in which 10 massive bone grafts were used. Bony union followed operation in all but one of these patients. The author believes that union can be anticipated in the majority of cases after this procedure. However in 3 instances refracture occurred following union. In one patient amputation was done after refracture. Bony union has been present following the second bone graft operation for 1 1/2 years, 2 years, and 3 1/2 years, respectively. Union has persisted after the first massive graft for 3 1/2, 7 1/2, and 22 years, respectively.

A refracture may be preceded by an increase in sclerosis about the fracture site, narrowing of a previously reformed medullary canal, or an insufficiency fracture. Routine follow-up roentgenograms should be made at intervals of 6 months, to determine if any of these factors are developing and, if so, surgical intervention may be indicated before a complete refracture occurs.

The authors emphasized the need for adequate bracing. This should be carried out following the bone graft until a new well developed medullary

canal has formed across the fracture site and until the tibia has reached sufficient size and strength to compare favorably with the normal one. This will usually require the use of a brace until the child is past puberty which in actual practice means a period of from 5 to 12 years.

It is the consensus that the older the patient, the greater the probability of union and that union is obtained with greater ease after puberty. However the longer the operation is delayed the more shortening will occur the leg will be poorly developed and the deformity due to anterior bowing of the leg and calcaneovalgus of the foot will be greater. It is the authors' opinion that the patient should be operated upon as early as practicable that is from 3 to 5 years of age.

At operation the surgeon should remember that the bone is small and osteoporotic. The dual graft forms a 'bone clamp' consequently it is easy to fracture the osteoporotic bone just above the ankle, at the lower end of the graft.

The type of brace advocated by Kite in which the leather sleeve laces posteriorly is superior to one laced down the front of the leg a solid well molded piece of leather on the anterior surface of the leg gives better support to the tibia, which usually has a tendency to become angulated in that direction.

Three types of patients with congenital pseudarthrosis are recognized those born with a defect in the tibia those with fractures developing in a congenital cyst of the tibia, and those born with congenital bowing of the tibia in whom the bone is small and sclerotic and the medullary canal is diminished in size, or absent. In the third type the tibia usually breaks as the result of minor trauma. Following the fracture absorption occurs and a typical pseudarthrosis results. In a patient of the third type, osteotomy to correct the bowing of the tibia should not be done as nonunion will develop.

The prognosis for fractures developing in congenital cysts is probably more favorable the bone is better suited mechanically for grafting because the ends of the bone are not narrowed and pointed as in the other two types. Also the medullary canal in both fragments is larger and consequently easier to expose and open. The choice between amputation and bone grafting may be a difficult one. It is necessary to compare the usefulness of an artificial limb with that of the extremity which can reasonably be expected after a successful bone graft, rather than with a normal leg. An expected shortening in excess of 3 inches a considerable residual deformity such as anterior bowing of the tibia and pes calcaneovalgus and the constant possibility of re-fracture of a small, weak tibia may be indications for an amputation. C. FRED GOEDOWSKI, M.D.

Primary Hemangiomas of Muscle. I W. KAPLAN and WILFRED E. TORRESON *Am. J. Surg.* 1942, 75, 614.

Hemangioma of the skeletal muscles is a relatively rare disease. In a series of 1,308 hemangiomas, Watson and McCarthy reported that 10 or 0.8 per cent,

occurred in skeletal muscle. Since the first reported hemangioma of skeletal muscle in 1843 some 353 cases have been reported.

The clinical picture is varied, depending upon the site of occurrence. Symptoms may persist from one year to several years. Pain, the most common symptom is localized at the site of the tumor it varies from a dull, aching fullness to a sharp throbbing sensation. The pain may be aggravated by exertion and will usually subside with rest. Palpation usually reveals a fixed mass which may be ill defined or sharply demarcated. The mass may feel fluctuant, soft, or firm more often it has a rubbery consistency. It is usually tender to deep pressure and pulsations may be detected.

The most common site of occurrence is in the muscles of the lower extremities although any striated muscle may be affected. One or several muscles may be involved.

The consensus is that hemangiomas are congenital and that trauma is frequently an important factor in activating the growth of the tumor and the development of symptoms. The condition must be differentiated from hematoma, fibroma, neurofibroma, fibrosarcoma, lipoma, hydatid cyst, myoblastoma, and rhabdomyoma. Exploratory puncture and roentgenologic studies are the most valuable aids in establishing a correct diagnosis. Phleboliths, shown by x ray films are present in about 48 per cent of the cases. Exploratory puncture reveals blood in approximately 98 per cent of the cases.

Surgical excision is the treatment of choice. The author reports a case which was of interest because the tumor involved the entire external and internal abdominal oblique muscles of the right abdominal wall, and hemangioma of muscle was considered in the differential diagnosis because of the presence of phleboliths.

C. FRED GOEDOWSKI, M.D.

Rare Sites of Primary Acute Osteomyelitis. Ribs, Sternum, and Skull (Sed rare di osteomielite acuta primitiva coste, sterno cranio) ALESSANDRO FICAL *Rass. internaz. clin. ter.*, 1948, 28, 44.

The author presents 3 cases of primary acute osteomyelitis. In the first patient a man 30 years of age the anterior portion of the sixth right rib was involved. The course was extremely favorable and the patient was cured in a little over one month. In 102 cases of osteomyelitis reviewed by Zampetti this localization was found only five times. In the second case a portion of the body and of the manubrium of the sternum was involved in a man 72 years of age and cure was obtained in about 40 days. The cartilage interposed between the two parts of the bone prevents the spread of infection from one part to the other its late ossification explains the rarity of this spread but in the present case the entire sternum consisted of compact bone hence the involvement of both body and manubrium. In the third case a woman 28 years of age, the left parietal bone was involved. The course of the process differed from that usually seen in osteomyelitis of the

skull it was mild during the first stage and the fever soon disappeared but 30 days after the disease began there was a second rather severe stage with meningeal symptoms which required a second intervention this was followed by improvement but 5 days later the meningeal symptoms reappeared and the general condition became bad another intervention was indicated but the family decided to take the patient home

In the last two cases the infecting agent was the staphylococcus in the first case no bacteriologic examination was made but the quality of the pus suggested the staphylococcus as the agent. The germs usually reach the bone by the blood route in the second case the original focus of infection was the first toe of the right foot and in the third case, the fifth finger of the left hand In the first case osteomyelitis followed a blow received in a boxing match one month previously

About 60 cases of acute osteomyelitis of ribs have been reported The disease nearly always occurs during the period of growth although quite a few cases have been observed in adults and even between the ages of 60 and 75. Osteomyelitis following typhoid fever is more frequent in adults, and it is observed in men more frequently than in women Usually only one rib is involved and the preferred points of attack are the nuclei of ossification In infancy the infection is usually in the anterior end of the rib in childhood and later it occurs especially in the posterior end in the cephalic point, and more often in the chondrocostal extremity The cartilage may take part in the process (osteochondritis) by spread from the adjacent bony focus or by way of the small well vascularized nuclei of ossification or of the perichondrium

About 30 cases of acute osteomyelitis of the sternum have been reported The most frequent localization is in the body of the bone, but the manubrium and the xiphoid process may be involved The abscess may work its way in various directions Mediastinal abscess is the most frequent complication then follow in frequency the invasion of the lungs and pleura

Not more than 40 cases of primary osteomyelitis of the skull have been reported. The bones most frequently involved are the frontal, parietal, temporal, and occipital The process begins in the diploe and spreads through the entire thickness of the tables the pus detaches the dura internally and the periosteum externally giving rise to intracranial extradural, and subperiosteal extracranial collections

The prognosis is generally benign for osteomyelitis of the ribs, as complications are rare. In osteomyelitis of the sternum the mortality seems to reach 50 per cent owing to complications. In osteomyelitis of the skull the prognosis is mostly unfavorable because of the local and general complications (purulent meningitis, thrombosis of the sinuses, cerebral or cerebellar abscess toxemia with degeneration of various organs septicemia, etc.) Treatment can

only be surgical preceded and followed by sulfonamide or penicillin therapy RICHARD KIMMEL, M.D.

Perthes Disease, Osteochondritis Dissecans, and Infantile Coxa Vara Experimentally Produced in Animals. EDUARD BURCHARDT *Helvet. chyr. acta*, 1945, 15: 3.

The cause of juvenile osteochondritis is still unknown Perthes' disease, osteochondritis dissecans, and coxa vara show similar histologic findings but affect different parts of the proximal end of the femur Coxa vara has its main pathology in the metaphysis while Perthes disease and osteochondritis dissecans affect the epiphysis predominantly Histologic sections show an irregular arrangement of new bone formation and aseptic necrosis

Since the work of Axhausen in 1920, a number of workers have tried to produce these conditions experimentally in animals by replacing excised fragments of the femoral head, but have failed. It is not known whether these experiments were carried out on adult animals or young animals

The author performed these experiments in order to ascertain whether the etiology of these conditions is (1) mechanical-traumatic or (2) spontaneous aseptic necrosis

In 1930, Nagura was able to experimentally produce osteochondritis of the femoral head of growing squirrels by causing an incomplete fracture of the articulating cartilage. By means of a carefully measured blow to the femoral head incomplete fractures of the cartilage, or of cartilage and subchondral plate or cartilage subchondral plate and part of the metaphysis were produced Depending upon the location of this blow Perthes' disease, osteochondritis dissecans, or coxa vara was produced

The author used repeated measured traumas to localized areas of the epiphysis or metaphysis. By directing the blows on the epiphysis, osteochondritis was seen after a lapse of 5 months. Following blows on the medial corner of adjoining portions of the epiphysis and metaphysis, coxa vara developed after about a year

It is possible that, in humans, repeated traumas to one area of the proximal end of the femur is the cause of these conditions and the insidious development of symptoms, however this theory does not answer all questions, i.e. why these conditions occur in certain families and in certain parts of the world, the hereditary factors and the role of endocrine dysfunctions (hypothyroidism)

Degenerative arthritis has a similar sequence of symptoms and end-results, as observed in Perthes' disease, except that it occurs in older people

GEORGE L. REIMS, M.D.

Evolution of Mould Arthroplasty of the Hip Joint. M. N. SHERR-PETERSON. *J Bone Surg* 1945, 30B: 59.

The present article is in substance the fourth Mowbray Lecture delivered by this author (May 1947) at the University of Leeds.

The article is accompanied by many excellent illustrations depicting the older hip joint approaches with their pitfalls and the Smith-Petersen procedure with its advantages.

In 1923 the author constructed and employed the first glass mould arthroplasty cup. To his amazement the mould broke on weight bearing. A specimen of the femoral head, removed 25 months after operation, revealed regeneration of hyaline cartilage the finding of which justified his continued interest in the cup arthroplasty. It was not until 1937 that his dentist, Dr. Cooke, suggested to him the use of a vitallium mould. Since then more than 500 hips have been treated with a cup arthroplasty in 80 patients the condition was bilateral.

The indications were as follows: (1) malum coxae senilis 90 cases; (2) rheumatoid arthritis 120 cases; (3) complication of fractured hips such as nonunion, aseptic necrosis and dead heads 50 cases; (4) old septic hips, 32 cases; and (5) congenital dislocations (50 hips). In the latter group 10 cases were bilateral.

Fifty-three of the 500 hips operated upon have been subjected to an additional revised arthroplasty. These secondary operations involved the earlier cases, in which an error in technique and judgment had been made. Other reasons for secondary operation were calcification of the rectus tendon at the inferior iliac spine, shallow acetabulum, decreased

range of motion, operative sepsis and intrapelvic protrusion of the acetabulum.

No deaths occurred in this large series of cases. Septic complications at the site of operation developed in 20 cases. SAMUEL L. GOVERNALL, M.D.

Pseudarthrosis in the Lumbosacral Spine. MATHER, CLEVELAND, DAVID M. BOSWORTH, and FREDERICK R. THOMPSON. *J. Bone Surg.* 1948 30-A 302.

The study of 647 fusion procedures on the lumbosacral spine carried out on 594 patients presented the problem of pseudarthrosis in 119 patients, or 20 per cent. The mortality and complications were of minor importance in these patients, all of which were operated upon by the three authors personally working in six different hospitals.

At 161 of the 1,350 spinal intervals bridged pseudarthrosis occurred. The incidence of pseudarthrosis increased as the area of fusion was lengthened. Of all the patients in whom pseudarthrosis developed 41.4 per cent were nonetheless relieved of their preoperative symptoms. In spite of solid fusion a number of patients were not relieved of their pain, especially those in whom only one or two intervals were bridged, or those whose lumbosacral junction was not crossed.

Flat roentgenograms are not adequate to show accurately whether or not pseudarthrosis is present.

Fig. 1 (Cleveland et al.) a, Two types of pseudarthrosis are shown, the usual transverse type and the type occurring at the end of a clothespin graft. b, Repair of such pseudarthrosis is carried out on one side only. Transverse processes and articular facets are exposed, and the site of previous fusion is denuded on its posterior surface only. c, A wide iliac strip is set vertically on the transverse processes

outside the articular facets and in contact with them. Strip grafts of ilium are then placed over the domum of the previous fusion on one side, in the angle between the fusion and the vertically placed graft. The remainder of the previous fusion on the opposite side is not even exposed, being shown in the illustration only for clarity. It is left alone for such support as the bony masses already provide.

Biplane bending films, superimposed, increased the accuracy of diagnosis of pseudarthrosis in this series from 11.8 to 50 per cent. A careful analysis of the relation of pseudarthrosis to the lesion for which arthrodesis was attempted, and of the various operative procedures used, indicates that least difficulty is encountered when only the lumbosacral interval is bridged. The use of additional re-enforcing bone at the fusion site reduces the incidence of failure of arthrodesis.

A mortality of only 1 per cent occurred in this series. Only 35 patients of the 119 in whom pseudarthrosis occurred returned to the authors for repair. The repair is appreciably more difficult than the original operation. A new type of repair is described and illustrated which avoids many of the factors of previous failure.

FRANCIS E. BRIDGEMAN, M.D.

Plantar Digital Neuritis; Morton's Metatarsalgia. K. I. NORDEN. *J Bone Surg* 94B, 308-84.

The neuralgic pain felt at the fourth metatarsophalangeal joint is known as a Morton's toe. Anatomically the innervation to the third and fourth digits is a dual one, namely the internal plantar nerve and a small communicating branch of the external plantar nerve. The latter may be inconstant. As a rule the above nerves are protected from trauma by being surrounded by plantar fascia and fat. The blood supply comes from the deep plantar arch and is adequate.

As far back as 1893 Hoadley resected a small neuroma of the external plantar nerve to the fourth toe and obtained a prompt and perfect cure. It was not until 1910 when Betts reported a series of cases of fibrosis of the epineurium of the internal plantar nerve to the third and fourth toes, that Sir Robert Jones and others recognized the Morton's phenomenon as a neurofibroma of the interdigital nerves to the second, third and fourth toes.

The author presents 37 interesting cases of metatarsalgia. In these patients (31 women and 5 men) the pain was generally felt between the third and fourth toes.

At operation, the nerve was exposed by a longitudinal plantar incision. Usually the nerve can be sought where it crosses the transverse ligament. If it is adherent to the latter structure and is obviously thickened, resection yields complete abolishment of the characteristic manifestations.

Histological examination of the specimen is predominantly an ischemic one.

Photomicrographic studies of the fibrous bulk reveal an increased epineurial connective tissue proliferation, degeneration of the nerve fibers, and degenerative changes of the digital artery with disruption of the arterial wall and incomplete recanalization thrombosis, and similar changes to the intra-neural vessels.

The coexistence of the thromboarteritis and the neurofibroma is not clear to the author.

SAMUEL L. GOVERNALE, M.D.

Tuberculosis of the Cuboid (Tuberculosis del cuboide). C. DE MAQUO. *Reforma med.*, 94B, 6: 15.

The author describes a rare case of tuberculosis of the cuboid bone in the foot of a woman 33 years of age. For a period of 4 years the patient had complained of pain on the dorsum of the foot, with nocturnal exacerbations. A month after the onset of pain she noted edema of the lateral surface of the foot, which was aggravated on standing. Hot compresses gave temporary relief; however, a month later a soft tumorous swelling the size of a walnut appeared. This finally broke down into an ulceration, with drainage of a purulent liquid. A fistulous tract resulted. In spite of treatment over a period of 3 years with a fenestrated cast, calcium iodide, and diathermy the subjective and objective symptoms remained the same. Seropurulent material exuded from the ulcer. Its margin was cyanotic in color and was undermined for a distance of 3 cm. Inguinal lymph glands were not palpable. Active and passive movement of the ankle joint was impossible.

Röntgen-ray examination of the foot revealed an accentuated deossification of all the bony components of the foot and the distal part of the leg. An irregular zone of rarefaction was present in the center of the cuboid.

The cuboid was surgically removed in pieces as it broke in the process of removal.

Gross examination of the fragments revealed a cortex diminished in thickness, with loss of the normal architecture while the spongy portion had a grayish color.

Histological examination revealed granulation tissue with numerous typical and atypical areas and also a zone of increased calcified osseous tissue.

The condition in this patient had to be differentiated from syphilis, chronic osteomyelitis, neoplasm, and actinomycosis.

In infancy these patients should receive good general care, heliotherapy and orthopedic treatment. In adolescence and thereafter a cuboidectomy should be done if there is no response to medical management.

SURGERY OF THE BONES, JOINTS.

MUSCLES, TENDONS, ETC.

Obturator Nerve Avulsion in the Treatment of Painful Hip Joints. EMANUEL B. KAPLAN. *Surg Clin. N. America*, 94B, 45-473.

Nerve endings and their behavior in articular and periarticular tissues have been studied by several investigators without establishing any conclusions.

Gross anatomical descriptions of the nerve supply to the hip seem to have been originally based on rather limited dissections, and repeated by one author after another. This anatomical background for the problems of painful hips leaves many clinical observations without adequate explanation and therefore without rational therapy.

The obturator nerve has a large articular branch from its posterior division, but various other fine

branches are known to exist though they are difficult to trace. Less recognized is the proximity of the femoral nerve to the head and neck of the femur. Compression of the femoral nerve can give pain on the inner aspect of the knee through the saphenous nerve. Of the many surgical procedures devised for the relief of pain about the hip, avulsion of the articular branches of the obturator nerve is attended with minimal risk, so suitable especially for older debilitated patients.

The author and assistants studied 52 specially dissected hip joints in cadavers and concluded that the anterior capsule is largely supplied from the obturator nerve. On this basis, obturator avulsion was done on 54 patients at the Hospital for Joint Diseases in New York. A preliminary test injection of novocain in the area of the obturator nerve was done on each patient. Relief of pain after injection was considered an indication for the surgical procedure. The femoral triangle approach was used and found simple and rapid in this group. Relief of pain was noted as soon as the patient recovered from anesthesia. The patients were out of bed in from 1 to 2 days. No sensory disturbance was noted in the medial thigh areas, and there was minimal interference with adduction. General improvement was noted in 67 per cent of the cases and good results (pain diminished so that the patient could walk) in almost one-third of the cases.

FRANCIS E. BRIDGEMAN, M.D.

The Results of Periarticular Arthrodesis of the Knee in Tuberculosis by the Putti Method (Sui risultati dell'artrodesi peri articolare secondo Putti nella del ginocchio). S. COLOMBANI. *Chir. org. mod.* 1947 51 1

Putti in 1933, published his results in 8 cases of tuberculosis of the knee in which he used fusion according to his method. Only 3 of these cases were followed up to a complete cure at the time of his original publication. Putti believed that the only certain cure for tuberculosis of the knee was solid ankylosis. He thought that an exarticular fusion was easier to do and did not sacrifice any leg length. With his method he made use of a tibial graft running from the front of the tibia into the intercondylar area of the femur. In this manner the tuberculous area was not disturbed and toxic phenomena were minimal.

The author presents his results in 16 cases of tuberculosis of the knee treated by this method in the period from November 10 1934 to August 19 1943. Only the final results are presented in this article. Fifteen cases were treated successfully.

Postoperatively all patients were immobilized in a plaster cast, in some the pelvis, leg and foot were included while in others circular casts extending from the groin to the toes were applied. The period of immobilization was from 3 to 12 months.

The article is illustrated with roentgenograms taken before and after surgery.

CARLO SCUDERI, M.D.

FRACTURES AND DISLOCATIONS

Contribution to the Biochemical Study of Bone and Callus in Fractures (Contribución al estudio bioquímico del hueso y del callo de fractura). E. CAVAYE, HAZEN and E. RUIZ-ORTIZ. *Valdés Santurio. Cirug. apar. locomotor* 1948 5 2

Variations were observed in the chemical composition of the callus in fractures treated with simple immobilization and in fractures treated by the method of Kuntscher.

Dogs were used in these experiments. A fracture through the femur was produced with a Phelps Gocht osteoclast and a Kuntscher nail was introduced through the trochanter. In the control series a transverse fracture was produced and the fragments were permitted to remain in good position. The dogs were then sacrificed on the twelfth, twentieth, thirtieth, fortieth, fiftieth and sixtieth days.

In order to study the mineral composition of the callus and bone at the site of the fracture, all soft parts were removed. The callus was then reduced to ashes in an electric oven. Dilute hydrochloric acid was used to dissolve these ashes and the resulting solution was used to test the various minerals.

Calcium composition was determined by the addition of ammonium oxalate which formed a precipitate of calcium oxalate. Inorganic phosphorus was determined by the Bell-Daisy technique. Anhydrous carbonate by the van Slyke method. Total nitrogen by the method of Kjeldahl and phosphatase by the method of Fiske and Subbarow.

In observing the phosphorus/nitrogen ratio, the author noted a progressive increase in mineralization during the first 12 days (11) and a value of 1.3 after a period of 60 days. The general reaction was the same in fractures in which pins had been used and in those which had been treated without the use of pins. The maximum demineralization was effected in 45 days followed by gradual recuperation.

Demineralization phenomena in the pinned limb were accentuated due to the presence of the steel stem but were only a little greater than in the unpinned one.

No appreciable difference was observed in the process of mineralization of the callus or the phosphatase activity. These facts clearly show that steel pins do not hinder mineralization of the callus.

ARTHUR F. CITOLLA, M.D.

Habitual Dislocation of the Shoulder H. OSMOND-CLARKE. *J. Bone Surg.* 1948 30B 19

Platt devised his operation in 1925 after having performed several Bankart operations. His operation consisted of sewing the distal portion of the divided subscapularis tendon to the cartilaginous remains of the glenoid margin, thus providing a primary barrier to redislocation of the humeral head as well as a check-strap to prevent complete external rotation. Then the proximal end of the divided tendon was overlapped and sutured to the anterior capsule, thus strengthening and shortening it. A similar procedure

was developed independently by the late Doctor Putti and his associates.

The technique as described by Osmond-Clarke is as follows:

An anterior approach is used, the skin wound curving inwards along the outer one-third of the clavicle then extending downwards for about 6 inches. It is important that this incision should skirt the medial edge of the tip of the coracoid process. The groove between the deltoid and the pectoralis major muscle is widely opened. The cephalic vein usually requires ligation. The next step is to expose the coracoid process and free the conjoined tendon of the coracobrachialis and the short head of the biceps. To do this adequately it is wise to divide the upper inch of the margin of the pectoralis major tendon, and particularly the attenuated expansion of it that runs upwards under the deltoid to reach the capsule of the joint. The tendon is freed on all aspects and divided close to the coracoid process, leaving a sufficient stump to facilitate subsequent repair. It is retracted downward by means of a stitch, but must not be pulled too vigorously or freed too extensively or the nerve supply may be damaged. The next step is to divide the tendon of the subscapularis muscle, which is done by first passing a blunt instrument beneath the tendon from above to below and dividing it one inch from its insertion. The capsule is opened at this point also. The glenoid rim is inspected from within the joint. The distal stump of the subscapularis tendon is then attached to the most convenient soft tissue structure along the anterior rim of the glenoid cavity, i.e. the labrum or the deep surface of the stripped capsule and subscapularis muscle. The anterior surface of the neck of the scapula should be roughened to insure that the sutured "tendocapsule" will adhere to it. The medial portion of the capsule is drawn outward so as to overlap the sutured tendon of the subscapularis, and the subscapularis muscle is then drawn outward and sutured to the scarified tissue in the region of the bicipital groove. This overlapping causes shortening of the muscle and should not be overdone. The arm should readily rotate outward to the neutral position.

The after treatment consists of the employment of a Velpeau type bandage for a period of 3 to 4 weeks, followed by exercises to redevelop muscle power and movement.

The author's results have been good, but no detailed analysis of his cases is presented. The article is accompanied by 9 excellent full color illustrations of the operative technique.

NEWTON C. MEAD, M.D.

Recurring Dislocation of the Shoulder W. E. GALLIE and A. B. LE MESURIER, *J Bone Surg* 94B, 30B, 9.

This article appears as one of 6 articles on the subject of recurring dislocation of the shoulder and was published as a résumé of a symposium at the Annual Meeting of the British Orthopaedic Association. The clinical features, operative findings and detailed fol-

low-up results in 641 recurrent anterior dislocations of the shoulder are reported.

The authors devised a fascial transplant for the reconstruction of an anterior ligament of the shoulder in 1936 and have used it in 175 consecutive cases, with only 7 known recurrences.

In a study of nearly 300 cases, the authors have made definite observations and have fabricated a typical history. They subscribe to the thesis of Bankhart that recurrent dislocation is secondary to failure of healing of avulsion of the anterior glenoid labrum and joint capsule of the neck of the scapula. In conjunction with their study, Professor J. C. B. Grant examined the shoulder joints of a large number of cadavers, and observed that sometimes the labrum is not attached to bone throughout, but only at intervals, and that a hook can be slipped under it, thus lifting it from the bone. Anomalies of this type may account for the ease with which the head of the humerus sometimes slips over the glenoid rim.

Regardless of the inciting cause, recurrence is the result of the loss of the normal obstruction to forward displacement of the head. The indications for treatment are clear, i.e. the repair of damaged ligaments or the construction of new ones.

The operation is performed through an anterior shoulder incision separating the deltoid and pectoralis major in the groove, the short head of the biceps and the coracobrachialis muscles are retracted inward, the lower border of the subscapularis is identified and retracted upward, the areolar tissue over the capsule is bluntly dissected and the anterior brim of the glenoid palpated, about one-half inch above its lower border a drill is passed backward, upward, and slightly outward through the head of the scapula, the long drill is passed through the soft tissue posteriorly until it may be palpated under the skin, a short incision is made and a strip of fascia lata 1 inch wide and 10 inches long is guided back through the hole and drawn from posterior to anterior, the trailing end of the fascia is knotted and oversown with silk to prevent the knot from untying, the fascial strip is pulled through the scapula until the knot is felt to engage the posterior surface of the scapula, a tunnel is made in the head of the humerus and the strip passed through and, lastly, guided through hole in the coracoid process where it is firmly attached. The new ligament is drawn sufficiently taut to limit external rotation of the shoulder about 35 degrees. Ultimately this limitation nearly disappears.

Postoperatively a sling is worn for one month for the prevention of external rotation and abduction. The patient then begins exercises and regains almost full range of motion in from 3 to 4 weeks.

Results have been gratifying and all patients have returned to their ordinary work. Eighty patients, in whom the condition occurred in the Armed Forces, were returned to duty and ultimately demobilized without pensionable disability.

Of the 7 recurrences, 5 followed severe violence that might have dislocated normal shoulder. Five

other recurrences were attributed to a technical defect in the operation and should not occur again. The statement is made that if the new ligament is attached to the neck of the scapula a little below the middle of the anterior edge of the glenoid the head of the humerus cannot slip forward.

KENETH H. SPOONER, M.D.

A Review of 180 Cases of Recurrent Dislocation of the Shoulder J. CRAWFORD ADAMS. *J. Bone Surg.* 1943, 30B 26

The present article is based on 180 cases and 159 operations. The author discusses the pathology, the mechanism of production and the operative treatment of recurrent or habitual shoulder dislocation.

Bankart believes the pathology is always the same, namely detachment of the glenoid labrum from the bone margin of the glenoid cavity in its anterior aspect. He does not think that bone changes in the humeral head are important.

Bone lesions occur more frequently than is generally supposed for they may exist without discovery by routine roentgen examination or even surgery. Roentgenographic examination with the arm sharply rotated internally will show the defect in the upper and outer margin of the humeral head or else a dense line of condensation extending down from the top of the humeral head parallel with the shaft representing compaction of the spongy bone. These lesions were present in almost the same percentage (82%) as the labrum detachment, which was present in 87 per cent of cases adequately examined. At surgery it was found to be present in all cases in which the labrum was not detached. This can produce dislocation because when the arm is externally rotated and abducted the flattened portion is in contact with the anterior rim of the glenoid and it can easily slip over. The mechanism of production as found in this series, varied as follows:

1. A fall on the abducted arm (very frequent)
2. A direct blow from behind acting on the head of the humerus (relatively infrequent)
3. Hyperextension of the abducted arm (infrequent)
4. Excessive external rotation in abduction straining the anterior capsule and tearing or stripping it from the scapular neck (infrequent)
5. Inferior dislocation by hyperabduction (rare)

Operative treatment. The Nicola operation was used early but has been generally discarded. The Putti Platt and Bankart operations are good, have proved reliable and have gradually replaced it. Thirty-six per cent of the Nicola procedures were followed by redislocation after an average period of 22 months. Mobility of the shoulder after this operation is very good, often normal and may be the reason for some of the redislocations. Also followed the Nicola procedure in 70 per cent of the patients.

The Bankart operation gives stability and pain-free function but does limit external rotation. In cases in which the glenoid labrum is found to be intact some other operation must be performed.

The Putti Platt operation in which the subscapularis tendon is attached to the soft tissues anterior to the scapular neck and the tendon is shortened by overlapping has been satisfactory as it gives stability and is painless. External rotation has been definitely limited in most cases. When redislocation has occurred it has been in patients in whom external rotation had been completely regained which suggests that the operation was incorrectly done.

Operative treatment aims at correcting or nullifying the two underlying lesions. The labral detachment is corrected by reattachment or by an anterior buttress of fibrous or bony tissue. The humeral head defects are nullified by prevention of external rotation which allows the flattened aspect of the bone to slide over the glenoid rim.

Recurrent Dislocation of the Shoulder A. L. EYRE. *Brook. J. Bone Surg.*, 1948 30B 39

In 17 operations for recurrent dislocation of the shoulder by the Bankart approach it was revealed that the cause of the dislocations was (1) some lesion of the anterior surface of the head of the humerus (2) a groove in the posterior surface of the head of the humerus, which made the dislocation possible with less anterior displacement or (3) both.

In nearly half (8) of the cases both causes were present. Bankart's lesion (labral detachment) was responsible alone in only 5 cases. The humeral groove alone was the cause in 3 and 1 case was due to partial detachment of the subscapularis distally at the lesser tuberosity.

To repair Bankart's lesion the author uses Bankart's operation but he has modified the technique of suturing the detached labrum to the glenoid. He makes two grooves in the anterior aspect of the scapular neck leaving a stout bridge of cortical bone coming right up to the lip of the glenoid between them. A suture is passed under this bridge and holds the labrum, periosteum and capsule firmly down in place. He uses a sucker to keep the wound dry, a special cutting hook to pass the suture and methods of retraction to make this procedure practicable.

When a humeral groove is present in addition to a lesion of the anterior support of the head of the humerus the same procedure is followed unless the dislocation is considered primarily due to the humeral groove. In the latter case a bone graft comprising the entire thickness of the iliac crest has been fixed with a screw to the anterior surface of the scapular neck. Careful anatomical closure is important.

After treatment consists in keeping the arm at the side from 4 to 6 weeks. This is followed by exercises to regain movement.

Symposium on Recurrent Dislocation of the Shoulder A. BERNARD PAIN, A. S. BLUNDELL, BANKART, P. NEWMAN, H. OSWOND-CLARKE, and C. PERKINS. *J. Bone Surg.*, 1943 30B 46.

A. BERNARD PAIN (Leeds) reviewed 45 operations for this lesion. The Henderson fascial sling was used

in 13 cases, in 9 of which this method of treatment failed. He believes that fascial-sling operations are without value and that tendon slings are better but are not reliable. The Nicola operation was done in 13 cases, with failure in one-third of them. The anterior bone block operation was done in 4 cases. There were no recurrences up to the time of this symposium. Other procedures have been carried out, but in too small a number of cases for proper evaluation.

A. S. BLUNDELL BANKART After 30 years experience with his own operation, this discussion states there has been no recurrence of the condition, nor serious interference with motion afterwards. There is a constant anatomical lesion consisting of a tearing of the fibrocartilage or the capsule from the bone, and the obvious thing to do is to put it back again. The bone must be prepared (freshened) for this in order that the tissue will unite with it. No permanent internal fixation is necessary because the tissues will unite in 6 weeks or less. A dental drill is used to place a single mattress suture in the glenoid and this solves the only difficult part of the operation. No shortening or tying down of the subscapularis is necessary or desirable.

The lesion causing recurrent dislocation is not always a detachment of the labrum, but often the capsule is torn from an intact labrum. Bankart's operation takes care of either type of pathology as the capsule is divided at the glenoid margin and the distal cut edge is fastened to the denuded bone. This eliminates "laxity" and prevents redislocation.

The frequent grooves of the humeral head are the result of, and not the cause of, the dislocation. If the capsule is firmly attached to the glenoid dislocation cannot occur regardless of the groove.

P. NEWMAN The Bankart suture, which is put through the joint so that the humeral head can be levered away, enables one to drill the holes in the anterior glenoid rim easily.

OSWORTH-CLARKE Detachments of the labrum are not present in 10 per cent to 25 per cent of the cases, and an operation should be devised for these. The Bankart operation is difficult to do, and an easier method of repair, which gives a good anterior block and at the same time limits external rotation so that the bone defect in the head of the humerus can not engage the glenoid margin seems to be the answer to this problem.

NEWTON C. MEAD, M.D.

Note on Recurrent Dislocation of Shoulder Joint.
REGINALD W. THOM-JONES. *J Bone Surg* 1948, 30B 49.

Basing his opinion on 71 operations for recurrent dislocation of the shoulder this author believes that the only reliable methods of repair are those which correct the defect of the glenoid labrum and reef the anterior caps. He of the joint (Bankart, Putti, Platt). Recurrence followed in only one of 53 such operations and this particular shoulder was repaired through a superior approach, while all of the others were repaired through an anterior exposure.

The technique of the superior approach is described in detail. It involves a sabre-cut incision centered on the acromioclavicular joint with osteotomy of the base of the acromion. The latter is reflected outward together with the clavicular origin of the deltoid and the musculotendinous cuff of the shoulder is incised in the line of its fibers. It provides a very good exposure for the study and repair of the glenoid lesions, often considered responsible for the dislocations. This is demonstrated by three excellent colored photographs. The technique described does not result in fibrosis and shortening or 'tying down' of the subscapularis tendon and the limitation of external rotation following surgery. The one recurrence in this series is believed to be due to this defect of the superior approach.

The author concludes that the most important virtue of Bankart's procedure is the fact that the anterior approach results in fibrosis and shortening of the anterior structures and limitation of external rotation. In cases in which there is a humeral head defect it is believed that repair of the glenoid labral defect alone is not sufficient.

NEWTON C. MEAD, M.D.

Bone Block for Recurrent Dislocation of Shoulder.
L. PALMER and A. WIDMER. *J Bone Surg* 1948, 30B 53.

The authors describe the Hyblotte Eden operation performed in 90 cases of recurrent dislocation of the shoulder. Sixty patients in this series (8 women and 52 men) have been selected for detailed study. The article is accompanied by roentgenograms, a diagram depicting the mechanism of the dislocation, case reports, and a diagrammatic sketch of the surgical technique.

The operative technique is simple. A 3 inch incision is made between the deltoid and the pectoralis major muscles. The subscapularis tendon is located and cut $\frac{1}{4}$ of an inch from its insertion and, by rotating the humeral head outward, the medial glenoid lip is visualized. With the aid of a rasp, a subperiosteal pocket is made for the reception of an iliac bone graft and the graft is placed adjacent to the medial portion of the glenoid lip to prevent recurrent dislocation of the humeral head.

In 27 cases, the pathological findings at operation were those of typical detachment of the labrum from the anterior glenoid rim. In 22 cases, the labrum was ruptured, with frayed flaps of the lower anterior part of the rim. In 5 cases and 4 cases respectively the changes were minimal or there were no changes at all and in 1 cases there was detachment of the labrum with capsular rupture of the whole anterior aspect of the rim.

The authors follow-up studies revealed that 53 of the 60 patients had obtained excellent results. Normal range of motion of the shoulder was observed in 43 cases and from 20 to 30 degrees restriction of motion was observed in 11 cases. Four patients (6.7%) experienced redislocation.

Fig. 2

Cartilaginous Cup Arthroplasty in Ununited Fractures of the Neck of the Femur JOHN ROYAL MOORE, *J Bone Surg* 1948, 30-A 313.

Since the use of internal fixation for femoral neck fractures, the incidence of nonunion has been greatly reduced. Because of the trauma of the fixation materials however, there is often gross distortion or defect of the ununited fragments. Aseptic necrosis of the femoral head continues to occur with some frequency.

Ununited fractures of the femoral neck may result as follows:

1. Nonunion with a viable head.
2. Nonunion with a viable head and complete or nearly complete absorption of one or both neck fragments.
3. Nonunion with absorption of the neck fragments and a devitalized head.

The surgical procedures best suited for use in all of these conditions are described and a modification of the Brackett operation devised by the writer in 1938 is presented. The meticulous technique of this procedure involves reaming out the femoral head until only a translucent cartilage cap remains. The femoral fragment is shaped to fit snugly into the cap and the leg maintained in wide abduction by a one and a half hip spica. Careful postoperative change of position and graduated active joint motion is carried out until weight bearing is permitted at the end of 10 weeks.

No operative deaths occurred, but from a patient dying 9 years after this procedure sections of the joint surface were obtained. Viable articular car-

tilage was reported from microscopic studies of sections of the femoral cap. Grossly the femoral cap could not be manually freed from the femoral stump in a specimen secured from a patient who died 3 weeks postoperatively on account of pulmonary embolism.

Of 11 cases which have been followed up for from 1 to 9 years, 9 showed excellent results. The average leg shortening was 3 cm. or less, and the range of motion quite satisfactory.

Pathologic Anatomy and Treatment of Fractures of the Lateral Condyle of the Tibia (Anatomie pathologique et traitement des fractures du plateau tibial externe) JEAN GOSSET *Mém. Acad. chir. Par.* 1947 73 670.

Seven patients with fracture of the external tuberosity of the tibia were treated by immediate open operation with elevation of the depressed central fragment (made up, as a rule, of that area of the joint surface which is not covered by the lateral meniscus) reapplication of the medially concave marginal fragment, and fixation of the whole, by a bolt passing through the fragments and held at each end by loosely applied disc-like end pieces. The material comprised 4 women of 36, 60, 38, and 43 years of age, respectively; the remaining 3 patients were men of 34, 36 and 60 years of age, respectively.

Following the operation the limb is immobilized for 8 days, then the patient begins the mobilizing exercises himself. At first he practices static con-

tractions of the quadriceps and 20 days later he begins passive flexion exercises of the joint. In only one case was it necessary to break up an obstruction to flexion (under anesthesia) in order to obtain flexion of the operated knee joint of more than 90 degrees. In all of the other patients flexion was attained, and the patient was able to walk without limp could stand easily, and even hop on the operative limb.

In the subsequent discussion MERLE DAVENPORT, who has been advocating late operation in the form of lateral osteotomy of the tibia below the attachment of the quadriceps tendon with insertion of a wedge-shaped bone implant to straighten up the joint surfaces after the fracture has been allowed to heal without correction other than orthopedic procedures, criticizes the author's method of excising the meniscus in order to get more room to get at the fracture and exhibits pictures and roentgenograms of a number of patients in whom, he maintains, Gosset's method could not be used.

GOSSET in his reply does not defend himself against the criticism aimed at his removal of the meniscus; however he does defend his method of early operation and bolting of the fragments and maintains that such cases as were shown by d'Aubigné are the exception, as all 7 of his series of unselected patients presented perfect functional results and only one patient, who had a comminuted fracture of both condyles of the tibia and should never have been operated upon, could be classed as having an unsatisfactory result.

JOHN W. BREIDEN, M.D.

The Treatment of Fractures of the Malleoli. An Experimental Study (Traitement des fractures de malleoles) HUBERT DE RUYSSER. *Helv. chir. acta* 1948, 15, 24.

It is remarkable how frequently nonunion of fractures of the medial malleoli is seen. In most instances it is due to incomplete reduction of the fractures. In these experiments an attempt was made to find the best possible position of the foot in the reduction of fractures of the malleoli. Three series of experiments on cadavers were carried out. In the first group the malleolar region was carefully dissected and, by means of a chisel and mallet, a fracture was created in a manner most frequently seen clinically. In some cadavers, all muscles about the foot and lower leg were cut.

It was concluded that muscle power and valgus and varus positions of the foot had little influence on the position of the fractures. As a rule plantar flexion was favorable for alignment of fractures of the lateral malleolus, dorsiflexion of the foot was favorable for medial malleolar fractures.

In the second series of experiments, a fracture was created by having the chisel cut through the undissected malleoli. The findings corresponded in general with the results obtained in the first series.

In the third series of experiments, a heavy clamp was utilized to produce the fracture. In all cases, the force necessary to create a fracture of the malleoli also ruptured the surrounding skin and soft parts. It was thus impossible to create conditions which would resemble those found in living human beings. In the final analysis, the absence of the fracture hematoma, the different ligamentous injuries in vivo and irregular fracture lines usually found in living human beings were taken into consideration.

It was found that complete reduction of the fracture was a prerequisite for good healing. Therefore even if extreme equinus or calcaneus position of the foot is necessary for good alignment of the fracture line it should be used. The same applies after internal fixation (screw) of fractures of the malleoli.

ORTHOPEDICS IN GENERAL

Orthopedic Appliances in the Rehabilitation of Patients with Spinal Cord Injuries. DONALD S. BICKERS. *N. England J. M.*, 1948, 338, 545.

The use of orthopedic appliances has helped greatly in the rehabilitation of patients with spinal cord injuries. Proper bracing is the cornerstone on which the ambulation program is built.

The spasm of an even, moderately well developed mass reflex, particularly in injuries of the thoracic and cervical cord, renders this goal unattainable. The sudden unpredictable stretch reflexes cause flexion or extension of the lower extremities and trunk, with precipitate loss of balance. The result is either a fall or a rescue by the instructor which offers a psychologic and mechanical hindrance to ambulation progress. Decubitus ulcers are an ever

present threat in paraplegic patients, frequently result when braces are forced on a markedly spastic subject.

Evaluation of numerous agents and procedures for the relief of spasm, employed in the treatment of 200 patients during the past year, indicate that the treatment of choice is the anterior rhizotomy described by Munro. With proper indications complete rhizotomy is carried out on complete cord lesions, and differential rhizotomy is done on partial cord lesions.

The function of the brace is not the support of body weight but the maintenance of normal postural relations through splinting action. In effect, the muscle groups responsible for maintaining the body in an erect, stable position are replaced by external mechanical supports with maximum retention of normal joint function.

In patients with partial lesions of the conus and cauda secondary to penetrating wounds at or below the first lumbar vertebra, the function of the brace is to substitute a compensatory force for the lost dorsiflexors of the foot and, if necessary, to stabilize the ankle. Such patients are adequately supported with the wire drop-foot brace, since no lateral stabilization of the ankle is required, otherwise this is best done with the double upright drop-foot brace which provides good bilateral support of the ankle joint and positive spring drop-foot correction.

The ability to maintain the legs in extension and consequently to maintain the body in erect posture is directly dependent upon the integrity of the quadriceps femoris muscle. These lesions occur predominantly in the lumbar cord segments but may be due to severe or complete transections of the cauda equina at or below the level of the third lumbar vertebra.

Injuries from the third lumbar segment or cauda equina, or both, that are so complete as to deprive the patient of the functions of supporting the body weight on the lower extremities will in some cases require the pelvic band extension. The additional factor involved is the loss of part or all of the function of the internal and external rotators of the thigh.

The hip joint of the brace must be placed at the proper level to obtain maximum function of that joint. Its position should be opposite the superior border of the greater trochanter, which is the point of exit of the transverse axis of the hip joint. When the joint is too high there is downward traction on the pelvic band as well as undue pressure on the anterior aspect of the thigh by the thigh band when the patient is in the sitting position. If the joint is placed too low there is an upward thrust on the pelvic band and pressure on the posterior aspect of the thigh. The pelvic band should fall midway between the crest of the ilium and the greater trochanter to avoid pressure over the bony prominences with possible decubitus ulcer formation.

Long leg braces with back brace attachments are limited to the highest levels of injury—that is generally those above the third lumbar vertebra. Its

ORTHOPEDICS IN GENERAL

Orthopedic Appliances in the Rehabilitation of Patients with Spinal Cord Injuries. DONALD S. BICKERS. *N. England J. M.* 1948, 238, 545.

The use of orthopedic appliances has helped greatly in the rehabilitation of patients with spinal cord injuries. Proper bracing is the cornerstone on which the ambulation program is built.

The spasm of an even moderately well developed mass reflex, particularly in injuries of the thoracic and cervical cord renders this goal unattainable. The sudden unpredictable stretch reflexes cause flexion or extension of the lower extremities and trunk, with precipitate loss of balance. The result is either a fall or a rescue by the instructor which offers a psychologic and mechanical hindrance to ambulation program. Decubitus ulcers are an ever

present threat in paraplegic patients, frequently result when braces are forced on a markedly spastic subject.

Evaluation of numerous agents and procedures for the relief of spasm, employed in the treatment of 200 patients during the past year, indicate that the treatment of choice is the anterior rhizotomy described by Munro. With proper indications complete rhizotomy is carried out on complete cord lesions, and differential rhizotomy is done on partial cord lesions.

The function of the brace is not the support of body weight but the maintenance of normal postural relations through splinting action. In effect, the muscle groups responsible for maintaining the body in an erect, stable position are replaced by external mechanical supports, with maximum retention of normal joint function.

In patients with partial lesions of the conus and cauda secondary to penetrating wounds at or below the first lumbar vertebra the function of the brace is to substitute a compensatory force for the lost dorsiflexors of the foot and if necessary to stabilize the ankle. Such patients are adequately supported with the wire drop-foot brace, since no lateral stabilization of the ankle is required, otherwise this is best done with the double upright drop-foot brace which provides good bilateral support of the ankle joint and positive spring drop-foot correction.

The ability to maintain the legs in extension and consequently to maintain the body in erect posture is directly dependent upon the integrity of the quadriceps femoris muscle. These lesions occur predominantly in the lumbar cord segments but may be due to severe or complete transections of the cauda equina at or below the level of the third lumbar vertebra.

Injuries from the third lumbar segment or cauda equina, or both, that are so complete as to deprive the patient of the functions of supporting the body weight on the lower extremities will in some cases require the pelvic band extension. The additional factor involved is the loss of part or all of the function of the internal and external rotators of the thigh.

The hip joint of the brace must be placed at the proper level to obtain maximum function of that joint. Its position should be opposite the superior border of the greater trochanter, which is the point of exit of the transverse axis of the hip joint. When the joint is too high there is downward traction on the pelvic band as well as undue pressure on the anterior aspect of the thigh by the thigh band when the patient is in the sitting position. If the joint is placed too low there is an upward thrust on the pelvic band and pressure on the posterior aspect of the thigh. The pelvic band should fall midway between the crest of the ilium and the greater trochanter to avoid pressure over the bony prominences, with possible decubitus ulcer formation.

Long leg braces with back brace attachments are limited to the highest levels of injury—that is generally those above the third lumbar vertebra. Its

distinguishing feature is lateral hip stabilization by functional replacement of muscle groups controlling the actions of the pelvis and lumbar spine.

Patients requiring only drop-foot braces approach most nearly the normal gait. They may use ultimately either one or two canes and walk almost normally except that they tend to proceed on a rather wide base with stoppage gait. The type of gait to be employed by patients with long leg braces will depend on the degree of function remaining in the thigh flexors. Should the thigh flexors be adequate to advance the legs even though not strong enough to support the patient's body weight, either the four-point or the more rapid two-point crutch gait is feasible. In either case the patient should also be taught the swing through, which is the most rapid of all gaits and may be required in situations in which speed is desirable as in crossing streets with traffic lights. Patients with pelvic band extension will not usually exhibit enough function to allow the two-point and four-point gaits and consequently must be taught the swing through with the preliminary temporary swing to gait. For patients requiring back braces, the only practicable gait for distance walking is the swing through, which is taught to all patients with the exception of those with lesions situated above the second thoracic segment that are so

severe as to cause gross impairment of arm function.
C. FRED GORDENWALL, M.D.

Autotransplantation of Joint Capsule; an Attempt to Desensitize Patients Suffering from Rheumatoid Arthritis. ILAKI NOVOTNY. *Acta med scand.* 1948, 139, 524.

Clinical observations directed the author's attention to the possibility that after certain operations upon patients with rheumatoid arthritis there appears a phase in which the patient shows signs of possible desensitization. On the presumption that the course of the disease is connected to a large extent with allergic phenomena, he has tried to produce a state of desensitization by means of a new operative method. This method consists of transplantation of the diseased tissue of the capsule preferably from the patient's knee joint subcutaneously to the lower umbilical region. In 11 of the 12 cases described, there appeared a favorable postoperative reaction with reduction of pain and swelling and furthermore an increase of mobility of the joints. One patient died of react and the transplanted tissue became necrotic.

Seven patients have remained in a markedly better condition during the follow-up period of 9 to 17 months.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Radioactive Sodium in Peripheral Vascular Disease Studies. BRYAN C. SMITH and EMMETT H. QUINCY
Surg. Clin. N. America, 1948, 23: 304.

Radioactive sodium was first used by the authors for diagnostic purposes in peripheral vascular diseases at Presbyterian Hospital, New York, in 1943. They have used it in approximately 800 cases. This isotope as previously reported has given diagnostic, prognostic, and therapeutic information of a high degree of accuracy which has been of great benefit to patient and clinician.

In studies of peripheral vascular disease in the feet and legs, the patient lies on his back with his feet well separated. The counter is placed against the sole of the foot and a measured amount of radioactive sodium, usually about 100 microcuries in 3 to 7 c.c. of sterile normal saline, is injected into an antecubital vein. Precautions are taken to see that all of the material gets into the vein and that neither the patient nor the injector is contaminated by it, if the latter is going to handle the counter. The times of the beginning and end of the injection are noted. Registration of the arrival of the radioactive material at the sole of the foot is made by an audible signal from the Geiger counter which has an adjustable circuit so that the counting rate can be kept at a convenient level. Before injection there is a low background count due to cosmic rays and the presence in the vicinity of the apparatus of the radioactive material to be injected. When this material traverses the circulatory system and reaches the foot the counting rate increases sharply in this manner the arm-to-foot circulation time can be measured.

As the radioactive sodium leaves the capillaries and enters the extravascular fluid in the foot build up to equilibrium is manifested by the increase in counting rate. The "build up curve" is plotted in counts per minute for 30 to 45 minutes starting immediately after the injection. The rate of build-up and its final result depend upon the degree of patency of either the main artery or collateral circulation or both which is synonymous with the degree and type of pathologic changes in the walls of the arteries. For patients with various vascular disorders the curves may be within above, or below the range of normal readings. The very low curve may be due to thrombosis caused by arteriosclerosis, thromboangitis obliterans, endarteritis and other similar pathologic conditions and emboli. The degree of obstruction is dependent upon the degree of pathologic change present in the vessel wall. A high reading may result from inflammation or increased local blood supply due to vasodilation after the removal of normal vasoconstriction following peripheral nerve block, sympathectomy, or idiopathic vasodilation as in erythromelalgia.

The authors do not attach as much clinical importance to the circulation time as might be the case were environmental conditions of temperature and those of the patients more constantly controlled. However a marked variance either a quickening or delay in the circulation time from that of normal as previously cited is of considerable clinical importance.

The authors present 15 cases with accompanying charts to illustrate the findings in various types of cases and to explain the diagnostic, prognostic, and therapeutic deductions made from the results of this method.

HERBERT F. THURSTON, M.D.

The Treatment of Pulsating Exophthalmos Due to Aneurysm in the Carotid Sinus (Sul trattamento dell'esoftalmo pulsante da aneurisma seno-carotideo). PAOLO BLOCCA. *Polidinicio sez. chir.* 1947, 54: 234.

The author presents a case of pulsating exophthalmos. The patient entered the hospital on January 15, 1944. During a bombardment 4 months before admission he had been buried under debris of a fallen home and was unconscious for about 2 hours. Following this injury he suffered with severe head aches most marked in the right frontal region accompanied by a continuous rhythmic humming (tunnel murmur) and diminished vision in the right eye. There had been some otorrhagia at the time of the accident. A tumorization developed rapidly in the region of the right eye with marked ecchymosis and as the ecchymosis and edema subsided there developed a complete ophthalmoplegia. In the beginning the external rectus had been functioning. The right pupil showed moderate mydriasis and reacted a little to direct and consensual stimuli. The fundus showed marked turgor of the central vein. On auscultation a dull murmur was heard in the right orbital and temporal region with marked systolic accentuation. Digital pressure on the carotid artery caused the murmur and the subjective symptoms to disappear. The blood pressure was 165/65 and the red blood count 5,860,000.

Radiologic examination revealed an extensive recent fracture which extended into the right frontoparietal temporal region and into the base. The right frontal sinus and ethmoidal cells were moderately opaque. Angiographic studies were made by rapid injections of thorotrast (12 c.c.) and roentgenograms were taken at intervals of 3 seconds, 6 seconds and 8 seconds. In none of these was a filling of the arterial cerebral circle noted. In the first picture the carotid siphon, the cavernous sinus, the superior ophthalmic vein—markedly dilated and tortuous—the angular vein and anterior facial vein were filled with the opaque substance. In subsequent pictures a rapid emptying of the cavernous sinus followed by the ophthalmic and the facial sinuses was observed.

A diagnosis of aneurysm of the carotid sinus was established. Since the condition did not respond to conservative therapy surgical intervention was necessary to produce a stenosis of the internal carotid. This was done by means of a large silk ligature. The immediate postoperative result was good with disappearance of symptoms and a rapid reduction of the exophthalmos. After a period of a week, however the symptoms recurred at first slowly but then more rapidly until they became as intense as before operation.

A second operation was performed at which complete ligation of the internal carotid was accomplished. The patient withstood the operation very well. In a few days there was subsidence of all the vascular symptoms as well as rapid improvement of the ocular palsy. Paralysis of the fourth nerve only persisted for some time. The pulse rate dropped from 84 to 68 and remained at 68. The patient was seen 3 years later at which time he was considered to be completely and definitely cured.

The literature is extensively reviewed and numerous methods of surgical intervention are described. The author outlines his choice of treatment which consists in medical management associated with manual compression, which is gradually increased. The results would probably be negative in which case he would perform ligation of the internal carotid artery in 2 stages. The second intervention should completely occlude the vessel should be accomplished with extreme prudence and eventually completed by ligating the internal jugular vein. If this is not successful intracranial ligation of the internal carotid and electrocoagulation of the ophthalmic arteries should be performed.

LOUIS J. FREEDMAN, M.D.

Oscillography and Arteriography for the Study of the Collateral Circulation in Arteriovenous Aneurysm (Circolo collaterale oscillografico ed arteriografico nell'aneurisma arteriovenoso) D. VOLTATI. *Ann. Ital. chir.* 947 241 S. L.

A 35 year-old military officer was struck by several fragments of an explosive shell. The tiny fragment entered the left arm up near the axilla and caused a vast tumefaction — later bloody discoloration and finally brownish discoloration of the skin of the region. A couple of weeks later it was observed that the resultant arteriovenous aneurysm had continued to enlarge rather rapidly with evidence of motor and sensory disturbances in the hand. This posed the question of urgent surgical interference. The oscillograph showed a fairly satisfactory circulation in the forearm and hand. Arteriography disclosed what appeared to be two aneurysmal sacs involving the brachial artery and vein. A tourniquet around the arm at the elbow improved the visualization of the vascular conditions so much that the collateral circulation, consisting of the profunda brachii artery and its branches, was clearly depicted.

At operation a ligature was passed around the brachial artery between the point of embolism of the

profunda brachii branch and the aneurysmal sack. At the same time the oscillographic tracing for the forearm was repeated and disclosed what the author believed to be an adequate collateral circulation although the hand appeared pale and pulseless. Therefore the arteriovenous aneurysmal sack, together with the two additional traumatic sacs were totally extirpated with ligation of both afferent and efferent arterial and venous communications (quadruple ligation). Following the operation the hand remained warm but no pulse could be felt however within a few days the radial pulse began to be appreciable and the sensory and motor disturbances rapidly improved. Five months later the extremity had entirely recovered and the patient was at his usual work.

The author regards 5 or 6 weeks as being the usual minimal period for the development of a satisfactory collateral circulation in arteriovenous aneurysms. In this case the use of the oscillograph during the operation after temporary ligation of the afferent artery permitted the satisfactory condition of the circulation to the hand to be demonstrated clearly and thus allowed of a precocious operation seemingly indicated by the developing neurovascular disturbances in the hand.

JOHN W. BUCKMAN, M.D.

The Treatment of Arterial Embolism. RICHARD WARREN and ROBERT R. LINTON. *N. England J. M.* 945, 384.

General conclusions concerning arterial emboli are that they usually occur in patients with heart disease who are in middle age, that the most common site of lodgment is a bifurcation of the femoral vessels, and that removal of the embolus before a period of 10 hours from onset has elapsed often, but not always, saves the limb. However improvements in conservative therapy—intermittent positive and negative pressure, intermittent venous occlusion, the oscillating bed, sympathetic block and anticoagulants—have relegated primary surgical attack to a secondary position.

The authors survey the records of 98 patients who suffered 7 arterial emboli during the period from 1937 to 1946 at the Massachusetts General Hospital, Boston. In 63.9 per cent of the patients the embolism occurred in the limbs. 88.7 per cent of the patients had a presumptive source of the emboli from within the heart, auricular fibrillation with auricular thrombosis was the major cause. The authors were unable to determine whether or not drugs to establish normal rhythm precipitated the embolism.

In the present series there were 46 females and 52 males. The average age of the patients was 57 with extremes of 22 years and 77 years. Arterial thrombosis and acute thrombophlebitis of the deep veins of an extremity must be considered in the differential diagnosis.

The authors devote the second half of their paper to a discussion of embolism to the arteries of the limb. If no treatment was instituted, 55 per cent of the affected limbs were saved. The prognosis in arterial emboli to the upper extremity is better than

that for arterial emboli to the lower extremity in the authors series all upper extremities were saved whereas 17 of 24 lower extremities were lost. Thus, the 55 per cent salvage for all limbs under no treatment is reduced to 29 per cent if only the lower limbs are considered.

The results with conservative measures (papaverine, paravertebral novocaine block, Pavax boot for the administration of intermittent suction and pressure intermittent venous occlusion and oscillating bed heparin) indicated a salvage of 25 limbs in 38 cases (65.8%) a similar analysis of emboli of the lower extremity indicated a salvage of 20 of 32 (62.5%) limbs. It was impossible to accurately evaluate the effectiveness of any one conservative measure.

Surgical treatment consisted of 25 operations on 21 patients for embolectomy 3 patients died so soon that evaluation of the effect of the operation was impossible. Of the 21 analyzable limbs 18 or 85.7 per cent survived. Thirty-eight of the 98 patients died in the hospital a mortality of 38.7 per cent, and all died of cardiovascular disease. It appeared that surgery itself was usually not harmful in these individuals.

Ten hours is considered the maximum period of grace for embolectomy to be successful. However surgery in peripheral embolism should not necessarily be abandoned because a temporal deadline has been passed. Much depends on the appearance of the limb. If actual gangrene has set in embolectomy is not to be considered. If however there is paralysis of the calf anesthesia of the foot, and marked vasospasm with a line of demarcation that is suggestive only embolectomy followed by conservative supportive measures should be performed.

The authors conclude that operation should be performed in all cases in which local anesthesia can be used, with the sole exception of popliteal emboli in which technical considerations intervene. Also aortic embolectomy is the treatment of choice for embolism of the aorta. Conservative treatment, although its results are good in some cases is justifiable only when the embolism obviously does not endanger the limb in the rare aortic embolism in which the patient is incapable of enduring the anesthetic and in popliteal embolism.

EDWARD H. CAMP M.D.

The Surgical Management of Venous Clotting
GERALD H. PRATT *Surg Clin N America*, 1948, 28
341

In surgery the pendulum of therapeutic opinion is seldom stationary but rarely is such an extreme oscillation encountered as is presently noted in the management of venous clotting. It is possible as pointed out by the author that sufficient time and experience have not elapsed to crystallize our therapeutic endeavors and therefore light our way

The clotting of blood occurs when the following conditions are present (1) an intrinsic change in the intravascular clotting factor (2) stasis and (3) tissue injury.

Other factors of importance are recognized and mentioned in this article. The predisposing factors of significance in venous clotting are (1) age (2) cardiovascular diseases (3) previous thrombosis (4) obesity (5) degenerating diseases and (6) fungus infections.

The author discusses the two types of venous clotting phlebotrombosis and thrombophlebitis. As a medical neologist he suggests that phlebotrombosis be called thrombosis, and in order to be consistent and avoid confusion of terms that thrombophlebitis be called thrombitis. This idea of simplification is indeed an important contribution to medical terminology.

The symptoms of thrombitis are listed in order of their frequency (1) pain at site and along vein, (2) redness along involved vein (3) swelling distal to inflammation, (4) tenderness along vein (5) fever (6) chills, and (7) leucocytosis.

Only 7 of the author's last 480 patients with thrombitis developed pulmonary embolism all of a minor type.

The symptoms of importance in thrombosis are listed in order of their significance in 90 patients with massive embolisms (1) pain usually in the popliteal space or calf (2) tenderness in the same area, (3) mild swelling (4) dilatation of veins over tibia, (5) cyanosis (6) increased pulse and temperature (7) sense of impending disaster (8) hypotension, and (9) embolism.

The author emphasizes the importance of prophylactic treatment. Weight reduction, abstinence from tobacco eradication of fungus infections correction of anemia, and early movement or ambulation are all discussed and considered to be necessary in the prophylaxis of venous clotting.

The active treatment of thrombosis is outlined as follows:

- 1 Vein resection (a) if early diagnosis (b) if anti coagulant therapy is ineffective (c) if embolism occurs (d) previous history of clotting (e) fear
- 2 Ambulation
- 3 Anticoagulant therapy dicumarol heparin early (contraindicated in some cases)
- 4 Thrombectomy if clot is higher than ligation point.

The active treatment of thrombitis is outlined as follows (1) paravertebral sympathetic nerve block, (2) anticoagulant therapy (3) mobility active and passive, (4) heat, and (5) sympathectomy occasionally.

The complications of edema, ulcer and dilated veins are mentioned in conclusion of this practical and concise program for treating the patient with venous clotting.

EDWARD F. LEWIS M.D.

A diagnosis of aneurysm of the carotid sinus was established. Since the condition did not respond to conservative therapy surgical intervention was necessary to produce a stenosis of the internal carotid. This was done by means of a large silk ligature. The immediate postoperative result was good, with disappearance of symptoms and a rapid reduction of the exophthalmos. After a period of a week, however the symptoms recurred at first slowly but then more rapidly until they became as intense as before operation.

A second operation was performed at which complete ligation of the internal carotid was accomplished. The patient withstood the operation very well. In a few days there was subsidence of all the vascular symptoms as well as rapid improvement of the ocular palsy. Paralysis of the fourth nerve only persisted for some time. The pulse rate dropped from 84 to 65 and remained at 63. The patient was seen 3 years later at which time he was considered to be completely and definitely cured.

The literature is extensively reviewed and numerous methods of surgical intervention are described. The author outlines his choice of treatment which consists in medical management associated with manual compression, which is gradually increased. The results would probably be negative in which case he would perform ligation of the internal carotid artery in stages. The second intervention should completely occlude the vessel should be accomplished with extreme prudence and eventually completed by ligating the internal jugular vein. If this is not successful intra-cranial ligation of the internal carotid and electrocoagulation of the ophthalmic arteries should be performed.

The Surgical Management of Venous Clotting.
GERALD H. PRATT, *Surg Clin N America* 1943, 23, 341.

In surgery the pendulum of therapeutic opinion is seldom stationary but rarely is such an extreme oscillation encountered as is presently noted in the management of venous clotting. It is possible as pointed out by the author that sufficient time and experience have not elapsed to crystallize our therapeutic endeavors and therefore light our way

The clotting of blood occurs when the following conditions are present (1) an intrinsic change in the intravascular clotting factor (2) stasis and (3) tissue injury.

Other factors of importance are recognized and mentioned in this article. The predisposing factors of significance in venous clotting are (1) age, (2) cardiovascular diseases (3) previous thrombosis (4) obesity (5) degenerating diseases and (6) fungus infections.

The author discusses the two types of venous clotting phlebotrombosis and thrombophlebitis. As a medical neologist, he suggests that phlebotrombosis be called thrombosis and, in order to thrombophlebitis be called thrombitis. This idea of simplification is indeed an important contribution to medical terminology.

The symptoms of thrombitis are listed in order of their frequency (1) pain at site and along vein, (2) redness along involved vein (3) swelling distal to inflammation, (4) tenderness along vein, (5) fever (6) chills and (7) leucocytosis.

Only 7 of the author's last 480 patients with thrombosis developed pulmonary embolism all of a minor type.

The symptoms of importance in thrombosis are listed in order of their significance in 90 patients with massive embolisms (1) pain, usually in the popliteal space or calf (2) tenderness in the same area, (3) mild swelling, (4) dilatation of veins over the area, (5) cyanosis (6) increased pulse and temperature, (7) sense of impending disaster (8) hypotension, and (9) embolism.

The author emphasizes the importance of prophylactic treatment. Weight reduction abstinence from tobacco eradication of fungus infections correction of anemia, and early movement or ambulation are all discussed and considered to be necessary in the prophylaxis of venous clotting.

The active treatment of thrombosis is outlined as follows:

1. Vein resection (a) if early diagnosis (b) if anticoagulant therapy is ineffective (c) if embolism occurs (d) previous history of clotting (e) fear
2. Ambulation.
3. Anticoagulant therapy dicumarol heparin early (contraindicated in some cases)
4. Thrombectomy if clot is higher than ligation point.

The active treatment of thrombosis is outlined as follows (1) paravertebral sympathetic nerve block, (2) anticoagulant therapy (3) mobility active and passive (4) heat and (5) sympathectomy occasion ally.

The complications of edema ulcer and dilated veins are mentioned in conclusion of this practical and concise program for treating the patient with venous clotting.

EDWARD F. LAWSON, M.D.

A diagnosis of aneurysm of the carotid sinus was established. Since the condition did not respond to conservative therapy surgical intervention was necessary to produce a stenosis of the internal carotid. This was done by means of a large silk ligature. The immediate postoperative result was good, with disappearance of symptoms and a rapid reduction of the exophthalmos. After a period of 3 weeks, however the symptoms recurred, at first slowly but then more rapidly until they became as intense as before operation.

A second operation was performed at which complete ligation of the internal carotid was accomplished. The patient withstood the operation very well. In a few days there was subsidence of all the vascular symptoms as well as rapid improvement of the ocular pulsation. Paralysis of the fourth nerve only persisted for some time. The pulse rate dropped from 84 to 65 and remained at 65. The patient was seen 3 years later at which time he was considered to be completely and definitely cured.

The literature is tentatively reviewed and numerous methods of surgical intervention are described. The author outlines his choice of treatment which consists in medical management associated with manual compression which is gradually increased. The results would probably be negative in which case he would perform ligation of the internal carotid artery in 2 stages. The second intervention should completely occlude the vessel should be accomplished with extreme prudence and eventually completed by ligating the internal jugular vein. If this is not successful intracranial ligation of the internal carotid and electrocoagulation of the ophthalmic arteries should be performed.

The Surgical Management of Venous Clotting.
GERALD H. PRATT *Surg Clin. N. America*, 1948, 28
347

In surgery the pendulum of therapeutic opinion is seldom stationary but rarely is such an extreme oscillation encountered as is presently noted in the management of venous clotting. It is possible, as pointed out by the author that sufficient time and experience have not elapsed to crystallize our therapeutic endeavors and therefore light our way

The clotting of blood occurs when the following conditions are present (1) an intrinsic change in the intravascular clotting factor (2) stasis and (3) tissue injury

Other factors of importance are recognized and mentioned in this article. The predisposing factors of significance in venous clotting are (1) age (2) cardiovascular diseases (3) previous thrombotic (4) obesity (5) degenerating diseases and (6) fungus infections

The author discusses the two types of venous clotting phlebotrombosis and thrombophlebitis. As a medical neologist, he suggests that phlebotrombosis be called thrombosis and, in order to be consistent and avoid confusion of terms, that thrombophlebitis be called thrombitis. This idea of simplification is indeed an important contribution to medical terminology.

The symptoms of thrombitis are listed in order of their frequency (1) pain at site and along vein (2) redness along involved vein, (3) swelling distal to inflammation, (4) tenderness along vein, (5) fever (6) chills and (7) leucocytosis

Only 7 of the author's last 480 patients with thrombitis developed pulmonary embolism, all of a minor type

The symptoms of importance in thrombitis are listed in order of their significance in 90 patients with massive embolisms (1) pain usually in the popliteal space or calf (2) tenderness in the same area, (3) mild swelling (4) dilatation of veins over tibia, (5) cyanosis (6) increased pulse and temperature (7) sense of impending disaster (8) hypotension, and (9) embolism.

The author emphasizes the importance of prophylactic treatment. Weight reduction, abstinence from tobacco eradication of fungus infections correction of anemia, and early movement or ambulation are all discussed and considered to be necessary in the prophylaxis of venous clotting

The active treatment of thrombitis is outlined as follows

1. Vein resection (a) if early diagnosis (b) if anticoagulant therapy is ineffective (c) if embolism occurs (d) previous history of clotting (e) fear
2. Ambulation.
3. Anticoagulant therapy dicumarol heparin early (contraindicated in some cases)
4. Thrombectomy if clot is higher than ligation point.

The active treatment of thrombitis is outlined as follows (1) paravertebral sympathetic nerve block, (2) anticoagulant therapy (3) mobility active and passive, (4) heat, and (5) sympathectomy occasionally

The complications of edema, ulcer and dilated veins are mentioned in conclusion of this practical and concise program for treating the patient with venous clotting

EDWARD F. LEWISON M.D.

A diagnosis of aneurysm of the carotid sinus was established. Since the condition did not respond to conservative therapy surgical intervention was necessary to produce a stenosis of the internal carotid. This was done by means of a large silk ligature. The immediate postoperative result was good, with disappearance of symptoms and a rapid reduction of the exophthalmos. After a period of 3 weeks, however the symptoms recurred at first slowly but then more rapidly until they became as intense as before operation.

A second operation was performed at which complete ligation of the internal carotid was accomplished. The patient withstood the operation very well. In a few days there was subsidence of all the vascular symptoms as well as rapid improvement of the ocular palsy. Paralysis of the fourth nerve only persisted for some time. The pulse rate dropped from 84 to 68 and remained at 68. The patient was seen 3 years later at which time he was considered to be completely and definitely cured.

The literature is extensively reviewed and numerous methods of surgical intervention are described. The author outlines his choice of treatment which consists in medical management associated with manual compression which is gradually increased. The results would probably be negative in which case he would perform ligation of the internal carotid artery in 3 stages. The second intervention should completely occlude the vessel should be accomplished with extreme prudence and eventually completed by ligating the internal jugular vein. If this is not successful intracranial ligation of the internal carotid and electrocoagulation of the ophthalmic arteries should be performed.

LOUEAN J. FROWDS, M.D.

Oscillography and Arteriography for the Study of the Collateral Circulation in Arteriovenous Aneurysm (Circulo collaterale oscillografia ed arteriografia nell'aneurisma arteriovenoso) D. VIO-DETTE. *Ann. Med. Chir.* 947 84. 5 L.

A 35 year-old military officer was struck by several fragments of an explosive shell. The tiny fragment entered the left arm up near the axilla and caused a vast tumefaction — later bloody discoloration and finally brownish discoloration of the skin of the region. A couple of weeks later it was observed that the resultant arteriovenous aneurysm had continued to enlarge rather rapidly with evidence of motor and sensory disturbances in the hand. This posed the question of urgent surgical interference. The oscillograph showed a fairly satisfactory circulation in the forearm and hand. Arteriography disclosed what appeared to be two aneurysmal sacs involving the brachial artery and vein. A tourniquet around the arm at the elbow improved the visualization of the vascular conditions so much that the collateral circulation consisting of the profunda brachii artery and its branches, was clearly depicted.

At operation a ligature was passed around the brachial artery between the point of emission of the

profunda brachii branch and the aneurysmal sack. At the same time the oscillographic tracing for the forearm was repeated and disclosed what the author believed to be an adequate collateral circulation although the hand appeared pale and pulseless. Therefore the arteriovenous aneurysmal sack, together with the two additional traumatic sacs were totally extirpated with ligation of both afferent and efferent arterial and venous communications (quadruple ligation). Following the operation the hand remained warm but no pulse could be felt however within a few days the radial pulse began to be appreciable and the sensory and motor disturbances rapidly improved. Five months later the extremity had entirely recovered and the patient was at his usual work.

The author regards 5 or 6 weeks as being the usual minimal period for the development of a satisfactory collateral circulation in arteriovenous aneurysms. In this case the use of the oscillograph during the operation, after temporary ligation of the afferent artery permitted the satisfactory condition of the circulation to the hand to be demonstrated clearly and thus allowed of a precocious operation seemingly indicated by the developing neurovascular disturbances in the hand.

JOHN W. BREDGAR, M.D.

The Treatment of Arterial Embolism. RICHARD WARREN and ROBERT R. LINTON. *N. England J. M.* 944, 35 4.

General conclusions concerning arterial emboli are that they usually occur in patients with heart disease who are in middle age, that the most common site of lodgment is a bifurcation of the femoral vessels and that removal of the embolus before a period of 10 hours from onset has elapsed often, but not always, saves the limb. However improvements in conservative therapy—intermittent positive and negative pressure, intermittent venous occlusion, the oscillating bed, sympathetic block and anticoagulants—have relegated primary surgical attack to a secondary position.

The authors survey the records of 98 patients who suffered 173 arterial emboli during the period from 1937 to 1946 at the Massachusetts General Hospital, Boston. In 63 per cent of the patients the embolism occurred in the limbs 88.7 per cent of the patients had a presumptive source of the emboli from within the heart auricular fibrillation with auricular thrombosis was the major cause. The authors were unable to determine whether or not drugs to establish normal rhythm precipitated the embolism.

In the present series there were 46 females and 51 males. The average age of the patients was 51 with extremes of 12 years and 77 years. Arterial thrombosis and acute thrombophlebitis of the deep veins of an extremity must be considered in the differential diagnosis.

The authors devote the second half of their paper to a discussion of embolism to the arteries of the limb. If no treatment was instituted, 55 per cent of the affected limbs were saved the prognosis in arterial emboli to the upper extremity is better than

that for arterial emboli to the lower extremity in the authors series all upper extremities were saved whereas 17 of 24 lower extremities were lost. Thus the 55 per cent salvage for all limbs under no treatment is reduced to 29 per cent if only the lower limbs are considered.

The results with conservative measures (papaverine, paravertebral novocaine block, Pavax boot pressure intermittent venous occlusion, and osseous bed heparin) indicated a salvage of 25 limbs in 38 cases (65.8%) a similar analysis of emboli of the lower extremity indicated a salvage of 20 of 33 (60.6%) limbs. It was impossible to accurately evaluate the effectiveness of any one conservative measure.

Surgical treatment consisted of 25 operations on 21 patients for embolotomy 3 patients died so soon that evaluation of the effect of the operation was impossible. Of the 21 analyzable limbs 18 or 85.7 per cent survived. Thirty-eight of the 98 patients died in the hospital a mortality of 38.7 per cent, and all died of cardiovascular disease. It appeared that surgery itself was usually not harmful in these individuals.

Ten hours is considered the maximum period of grace for embolotomy to be successful. However surgery in peripheral embolism should not necessarily be abandoned because a temporal deadline has been passed. Much depends on the appearance of the limb. If actual gangrene has set in embolotomy is not to be considered. If however there is paralysis of the calf anesthesia of the foot, and marked vasospasm with a line of demarcation that is suggestive only embolotomy followed by conservative supportive measures should be performed.

The authors conclude that operation should be performed in all cases in which local anesthesia can be used, with the sole exception of popliteal emboli in which technical considerations intervene. Also aortic embolotomy is the treatment of choice for embolism of the aorta. Conservative treatment, although its results are good in some cases is justified only when the embolism obviously does not endanger the limb in the rare aortic embolism in which the patient is incapable of enduring the anesthetic and in popliteal embolism.

EDWARD H. CAMP M.D.

The Surgical Management of Venous Clotting.
GERALD H. PRATT *Surg Clin N America* 1948 23 341

In surgery the pendulum of therapeutic opinion is seldom stationary but rarely is such an extreme oscillation encountered as is presently noted in the management of venous clotting. It is possible as pointed out by the author that sufficient time and experience have not elapsed to crystallize our therapeutic endeavors and therefore light our way.

The clotting of blood occurs when the following conditions are present (1) an intrinsic change in the intravascular clotting factor (2) stasis and (3) tissue injury.

Other factors of importance are recognized and mentioned in this article. The predisposing factors of significance in venous clotting are (1) age (2) cardiovascular diseases (3) previous thrombosis (4) obesity (5) degenerating diseases and (6) fungus infections.

The author discusses the two types of venous clotting phlebotrombosis and thrombophlebitis. As a medical neologist he suggests that phlebotrombosis be called thrombosis and, in order to be consistent and avoid confusion of terms that thrombophlebitis be called thrombitis. This idea of simplification is indeed an important contribution to medical terminology.

The symptoms of thrombitis are listed in order of their frequency (1) pain at site and along vein (2) redness along involved vein (3) swelling distal to inflammation, (4) tenderness along vein, (5) fever (6) chills, and (7) leucocytosis.

Only 7 of the author's last 480 patients with thrombitis developed pulmonary embolism, all of a minor type.

The symptoms of importance in thrombosis are listed in order of their significance in 90 patients with massive embolisms (1) pain, usually in the popliteal space or calf (2) tenderness in the area (3) mild swelling, (4) dilatation of veins over tibia, (5) cyanosis (6) increased pulse and temperature (7) sense of impending disaster (8) hypotension, and (9) embolism.

The author emphasizes the importance of prophylactic treatment. Weight reduction abstinence from tobacco, eradication of fungus infections correction of anemia and early movement or ambulation are all discussed and considered to be necessary in the prophylaxis of venous clotting.

The active treatment of thrombosis is outlined as follows:

1. Vein resection (a) if early diagnosis (b) if anticoagulant therapy is ineffective (c) if embolism occurs (d) previous history of clotting (e) fear
2. Ambulation
3. Anticoagulant therapy dicumarol heparin early (contraindicated in some cases)
4. Thrombectomy if clot is higher than ligation point.

The active treatment of thrombitis is outlined as follows (1) paravertebral sympathetic nerve block, (2) anticoagulant therapy (3) mobility active and passive, (4) heat, and (5) sympathectomy occasionally.

The complications of edema, ulcer and dilated veins are mentioned in conclusion of this practical and concise program for treating the patient with venous clotting.

EDWARD F. LEWIS M.D.

A diagnosis of aneurysm of the carotid sinus was established. Since the condition did not respond to conservative therapy surgical intervention was necessary to produce a stenosis of the internal carotid. This was done by means of a large silk ligature. The immediate postoperative result was good with disappearance of symptoms and a rapid reduction of the exophthalmos. After a period of a weeks, however the symptoms recurred at first slowly but then more rapidly until they became as intense as before operation.

A second operation was performed at which complete ligation of the internal carotid was accomplished. The patient withstood the operation very well. In a few days there was subsidence of all the vascular symptoms as well as rapid improvement of the ocular palsy. Paralysis of the fourth nerve only persisted for some time. The pulse rate dropped from 84 to 68 and remained at 68. The patient was seen 3 years later at which time he was considered to be completely and definitely cured.

The literature is extensively reviewed and numerous methods of surgical intervention are described. The author outlines his choice of treatment which consists in medical management associated with manual compression, which is gradually increased. The results would probably be negative in which case he would perform ligation of the internal carotid artery in 2 stages. The second intervention should completely occlude the vessel should be accomplished with extreme prudence and eventually completed by ligating the internal jugular vein. If this is not successful intracranial ligation of the internal carotid and electrocoagulation of the ophthalmic arteries should be performed.

LOUIE J. FRANKLIN, M.D.

Oscillography and Arteriography for the Study of the Collateral Circulation in Arteriovenous Aneurysm (Circolo collaterale oscillografico ed arteriografico nell'aneurisma arteriovenoso) D. VEDRIZ. *Ann. Ital. chir.* 947 84 5

A 25 year-old military officer was struck by several fragments of an explosive shell. The tiny fragment entered the left arm up near the axilla and caused a vast tumefaction—later bloody discoloration, and finally brownish discoloration of the skin of the region. A couple of weeks later it was observed that the resultant arteriovenous aneurysm had continued to enlarge rather rapidly with evidence of motor and sensory disturbances in the hand. This posed the question of urgent surgical interference. The oscillograph showed a fairly satisfactory circulation in the forearm and hand. Arteriography disclosed what appeared to be two aneurysmal sacs involving the brachial artery and vein. A tourniquet around the arm at the elbow improved the visualization of the vascular conditions so much that the collateral circulation, consisting of the profunda brachii artery and its branches, was clearly depleted.

At operation a ligature was passed around the brachial artery between the point of emission of the

profunda brachii branch and the aneurysmal sack. At the same time the oscillographic tracing for the forearm was repeated and disclosed what the author believed to be an adequate collateral circulation, although the hand appeared pale and pulseless. Therefore the arteriovenous aneurysmal sack, together with the two additional traumatic sacs were totally extirpated with ligation of both afferent and efferent arterial and venous communications (quadruple ligation). Following the operation the hand remained warm but no pulse could be felt however within a few days the radial pulse began to be appreciable and the sensory and motor disturbances rapidly improved. Five months later the extremity had entirely recovered and the patient was at his usual work.

The author regards 5 or 6 weeks as being the usual minimal period for the development of a satisfactory collateral circulation in arteriovenous aneurysms. In this case the use of the oscillograph during the operation, after temporary ligation of the afferent artery permitted the satisfactory condition of the circulation to the hand to be demonstrated clearly and thus allowed of a precocious operation seemingly indicated by the developing neurovascular disturbances in the hand.

SURGICAL TECHNIQUE

ANESTHESIA

Studies on the Parenteral Administration of Hydrogen Peroxide. A. L. LORINCZ, J. J. JACOBY and H. M. LIVINGSTON. *Anesthesiology* 948, 9: 163

This investigation revealed that in animals with sufficient blood catalase, hydrogen peroxide can be given intravenously with effects similar to those following the intravenous administration of oxygen. Significantly larger amounts of oxygen, however are tolerated in the form of hydrogen peroxide. The intravenous method of administering hydrogen peroxide is quite simple and the dosage can be readily controlled.

In animals very little therapeutic value could be established for the intravenous administration of hydrogen peroxide. It must be recalled, however, that in animals similar poor results are reported for the intravenous administration of oxygen, while in man clinically beneficial results are recorded. Therefore, it seems indicated that further cautious clinical experiments be carried out with the intravenous administration of hydrogen peroxide as a substitute for the intravenous administration of oxygen.

MARY FRANCES POE, M.D.

Infiltration Anesthesia in Inflamed Tissues (Die Infiltrationsanästhesie im entzündeten Gewebe) ARVID MORICZ. *Arch. Fowch.* 947: 1: 303, 316.

The literature abounds with warnings that local anesthesia in the form of an infiltration technique should not be used in inflamed tissues. The author says that his experiences in war surgery and then in civil practice, have not found these warnings valid. Both the inability of the inflamed tissues to become anesthetized and the possible ill effects of the local infiltration of anesthetic media have been used as reasons for a voiding infiltration methods in infected tissues. The author believes that these warnings have been based purely on theoretical grounds.

In a review of the literature and his own investigations, the author states that the pain which occasionally follows the infiltration of an anesthetic in an inflammatory field is due to a lack of isotonicity and a difference in the pH of the injected medium. This can be overcome by the use of freshly prepared solutions of the anesthetic medium which can be properly buffered. The objection that the medium will be more rapidly absorbed by the hyperemic tissues is more theoretical than real, according to experiments quoted by the author. He dwells much on the theory that the infection may of itself spread the bacteria and infected material. This, he states, is not the case. In most of the instances of infection, the tissues are almost immediately drained by incision, so that there need be no danger from spread. The para-aminobenzoic acid factor which renders the procaine infiltrated tissues less susceptible to the

action of the sulfa drugs, can be avoided by the use of pontocaine which does not possess this factor. Furthermore, the author believes that the local anesthetic has a beneficial effect on the tissues in alleviating pain. The pain, in his opinion is not caused so much by the hydrostatic pressure of the emulsi, but rather by the irritant action of the protein particles in the nerve endings. By obviating this pain vasodilatation takes place and the infection is further combated.

Several precautions were observed by the author in his series of almost 3,000 cases. The solution was always freshly prepared, and the syringes and needles carefully sterilized in distilled water so that they would not be alkaline. Adrenaline was used in all instances. The injections were made very slowly into normal tissues, especially into the skin and subcutaneous tissues. After the infiltration a waiting period of at least 10 minutes was employed to insure anesthesia. Dilute solutions were used in the bladder, rectum, and bronchi, as absorption in these areas is especially enhanced.

WILLIAM C. BUCK, M.D.

Pentothal-Curare Solutions: A Preliminary Report and Analysis of Its Use in 168 Cases. JOE W. BAKER, WADE E. JOHNSON and FREDERICK H. VAN BERGE. *Anesthesiology* 948, 9: 14

Pentothal-curare solution in combination with nitrous oxide has been used as a general anesthetic in more than 400 cases. This solution contains 5 units of d-tubocurarine chloride and 23.75 or 25 mgm. of pentothal sodium per cubic centimeter.

The authors have been greatly impressed by the adaptability of this anesthetic to practically all types of procedure, particularly those lasting over 30 minutes. At the present time it is believed that this is the general anesthetic of choice in the elderly, chronic, debilitated patient, and in extremely poor risks.

The complications arising during this anesthesia were relatively few. The most distressing one was hiccup. In a few cases extensive salivation was encountered. Foremost among the advantages is the minimal effect upon the cardiac conduction mechanism. Another outstanding advantage of this combined anesthetic is the elimination of explosion hazards.

A history of asthma or the presence of myasthenia gravis is considered a contraindication to the use of pentothal-curare solution.

MARY FRANCES POE, M.D.

The Influence of Posture on Mechanics of Respiration and Vital Capacity. CHARLES RONALD STEVEN. *Anesthesiology* 948, 9: 134.

A recent theory of pulmonary mechanics shows that the outward movements of the thoracic wall are of prime importance in expansion of the lungs. As a result of posture on the operating table, external

pressure may be applied in such a way as to prevent normal expansion. Tests with normal healthy individuals showed that the vital capacity varies according to the posture of the subject. The influence of gravity on the relaxed individual was noted as well.

Certain measures which tend to offset the deleterious effects of posture and gravity have been described. Sponge rubber chest and abdominal supports allow freer movements of the chest and abdomen when the patient is in the prone position. Elevation of the lower extremities compensates for the effect of gravity when the patient is in the upright position.

MARY FRANCES POZ, M.D.

Rationale and Hazards of Pressure Breathing and Oxygen Therapy H. W. RYDER and R. A. KENOR. *Anesthesiology* 1948, 9, 21

Inhalation therapy with oxygen has become a major item in general therapy as attested to by the tenfold increase in consumption of medical oxygen during the period from 1930 to 1947. The authors ask two significant questions concerning this trend: (1) "Is there justification for the emphasis being placed upon oxygen therapy?" (2) "Are there hazards from administering oxygen indiscriminately?" In clarifying these questions, they present a discussion of their experimental observations on healthy adults and on diseased patients. They point out that cerebral oxygen uptake is not improved materially by excess oxygen in the environment if some specific condition prohibits this uptake.

Physiologic effects of oxygen and pressure breathing in health and in illness are discussed. In the healthy subject increase of alveolar oxygen tension leads to increased arterial oxygen tension with an increase in carbon dioxide tension of arterial blood. The carbon dioxide combining power of venous blood increases also. Superatmospheric oxygen tensions in animals have been shown to give increased carbon dioxide tension in arterial blood. The authors believe this is best explained by the retention of carbon dioxide due to lessened sensitivity of the respiratory centers to carbon dioxide in the presence of high oxygen tension. When oxygen is given in sufficiently high concentration for hours or days it depresses slightly the oxygen carrying capacity of the blood and has uniformly toxic effects upon animals and certain toxic effects upon representative groups of healthy men."

Pressure breathing can actively inflate the lungs, but cardiac output is uniformly reduced in healthy men and syncope is more easily induced. At the same time apnea is more or less difficult to avoid during pressure breathing. Pressure on the heart and great

vessels is increased and thereby venous return and pulmonary edema are decreased.

In clinical application one finds that specific types of anoxia require specific therapy. Oxygen is often used empirically on the basis that it is the 'common denominator' of anoxic states. However the authors believe that the value of this 'common denominator' remains to be shown since oxygen is not always common to biologic oxidations.

In conclusion the authors suggest that the treatment of anoxic states usually requires more than oxygen therapy. They believe the foremost hazard of oxygen therapy is the neglect of the primary cause of the anoxia. As the principal value of pressure breathing is related to decreasing venous return to the right heart, pulmonary edema is one of the primary indications for such therapy.

MARY KARP, M.D.

Anesthetic Problems in Thoracic Surgery ELMER R. MAUREL. *Anesthesiology* 1948, 9, 183

In candidates for thoracic surgery the stage is already set for a complicating anoxic anemic anoxemia and postoperative shock. The demand for oxygen will be great and the dangers of suffocation constantly confront the anesthesiologist. Careful attention to patency of the airway, adequate oxygenation during anesthesia, and the replacement of blood as it is lost during the operation will do much to prevent anoxia.

In the opinion of the author nitrous oxide, oxygen and ether administered endotracheally through a closed apparatus, constitute the preferred anesthetic.

MARY FRANCES POZ, M.D.

Neosynephrin Hydrochloride in Anesthesia and Shock GEORGE J. THOMAS and PAUL A. SICA. *Curr Res Anesth* 1948, 27, 101

From their study on the use of neosynephrin hydrochloride the authors are of the opinion that this compound represents the most suitable of the vasoconstrictor substances. It does not produce stimulation of the central nervous system nor increase the irritability of the conducting tissues in the heart. This is the only known sympathomimetic compound that is safe for use with cyclopropane anesthesia or any other anesthetic agent.

They have found that venoclysis with glucose and neosynephrin solution is the surest way to maintain the blood pressure within normal limits during spinal analgesia. Nausea and vomiting usually present are practically nonexistent. Sufficient pentothal is administered to provide analgesia. The apparatus used is described.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Vasokymogram and Vascular Flow (Vasokymogramm und Gefäss-d räum) M. ZEHNDER. *Hefet. chir. acta* 1943, 3 63.

Despite the drawbacks due to the presence of the image of the screen, kymography is the simplest method to demonstrate on one film the passage of contrast medium through the vessels during a certain period. In addition, it allows temporal measurement of the flow and this may be valuable for the diagnosis of pathologic vascular changes (retardation in the cerebral pressure, vascular choking in the vicinity of the tumor, retention of contrast medium in the area (ter disappearance from the principal vessels).

The specific advantage of kymography lies in the possibility of following the passage of a small amount of contrast medium over a prolonged exposure time and thereby demonstrating the arterial as well as the venous flow on the same film. This broadens the diagnostic possibilities. Delays in the blood flow within organs can thus be clearly observed, for instance at sites of pathologic vascular proliferations as in tumors.

Zehnder has used a horizontally running kymograph with electric motor drive (the rapidity of which could be regulated for various predetermined periods). In experiments on rabbits he has used 7 seconds for the demonstration of the vessels of the extremities. For the human head the period is limited by the capacity of the tube which must work under a higher load to penetrate the bones of the cranium. Up till now he has reached periods of from 3 to 4 seconds from 5 to 6 seconds would be ideal to demonstrate the entire passage of contrast medium through the cerebral vessels. By preliminary injection of the medium in the usual amount it is possible to obtain a complete arterial picture and in addition, to catch also the capillary phase and the venous filling during the subsequent 3 to 4 seconds. The pictures obtained in model and animal experiments are a great help in determining the time taken by the passage of the contrast medium.

In one of the animal experiments, in which Zehnder made an involuntary retrograde injection of the descending aorta, he obtained a picture of the arterial and venous vascular system of the left kidney. From this he concluded that vasokymography could be used for renal diagnosis in appropriate cases. By compressing the aorta distally from the origin of the renal arteries and injecting the medium proximally into the aorta, it should be possible to demonstrate the renal circulation. The diagnostic advantages of such a performance are evident, as it would serve to determine the size of the organ, deformities, vascular anomalies and certain pathologic changes.

The author cites 2 cases. In the first 40-year-old woman had severe localized, frontoparietal head

aches on the left side and a normal encephalogram. The arteriogram and the kymogram showed no special vascular connection with the localized frontoparietal shadow seen in the left hemisphere and imitating convulsions here and there. This was localized Sturge-Weber disease (subcortical calcification) without vascular participation. In the second case there was a 54 year-old woman with a round cell sarcoma below the left elbow: the kymogram taken over a 5 second period showed clearly the vascular relations of the tumor and its vicinity and the venous return flow. RICHARD KERN, M.D.

A Subdural Hematoma Outlined with Air in the Encephalogram. OLUF OLSSON. *Acta radiol. Stockh.* 1943, 20, 95.

A case of a verified subdural hematoma is presented in which a small amount of subdural air was made to outline the hematoma by an appropriate change in the position of the patient's head. The usual methods of encephalography and ventriculography do not show pathognomonic signs of this condition. However, one case described by Dyke in 1936 was an exception.

The author's case was a typical one of subdural hematoma, namely, trauma was followed 2 months later by signs and symptoms of increased intracranial pressure, with localizing signs placing the lesion on the right side of the patient's head in the parietal region. Encephalography showed the septum pellucidum to be displaced 3 cm. to the left of the midline. The entire right lateral ventricle was pushed in under the falx cerebri, and the right inferior horn was displaced slightly medially. Air was present subarachnoidally over the left hemisphere. The greater part of the subarachnoid space over this right hemisphere showed no filling. A small amount of air was present in the subdural space over the convexity. On tilting of the patient's head to the left the subdural air on the right side moved lateralward, and formed a curved column of air with the concavity facing lateralward. Lateral to this column of air was a dense homogeneous area with a convex medial outline. Operation confirmed that this column of air outlined a subdural hematoma.

The author believes that the air in this case entered the subdural space through a rupture of the arachnoid. He suggests that a rupture of this kind may be caused by absorption of the hematoma. When absorption sets in, adhesions between the inner membrane of the hematoma and the arachnoid may lead to rupture of the arachnoid. The subdural space caused by this absorption does not fill in immediately but the air enters it, and in this way surrounds the hematoma.

The author presents this as a pathognomonic encephalographic picture of a subdural hematoma.

JOHN W. HOFF, M.D.

Pneumoencephalographic Diagnosis in the Presenile Dementias. PAUL CRODORFF, ALEXANDER SIDON and WALTER FREEMAN. *Am. J. Roentg.* 1948, 59 332

The authors have reviewed the literature with regard to the encephalographic diagnosis of the presence or absence of presenile dementia and the differential diagnosis between Pick's disease and Alzheimer's disease. It had been thought by some authors that these two diseases could be distinguished by ventricular dilatation and characteristic distribution of abnormal cortical air, while others had not been of this opinion.

Nine cases are presented, in which the pneumoencephalogram was evaluated both in the delimitation of the presenile group from other cases and in the differential diagnosis of Pick's disease and Alzheimer's disease. In all cases the diagnosis of presenile dementia was made on the basis of a progressive organic dementing process without evidence of any other etiology. Eight of the 9 patients died and autopsies were performed.

The air study revealed ventricular dilatation in all cases. In 7 of the 9 cases very little extracortical air was visible and no conclusion could be drawn as to the presence or absence of localized extracortical air. In 2 cases large collections of air prevented the appearance of cortical atrophy. Examination at autopsy confirmed the ventricular dilatations but did not demonstrate cortical atrophy in the suspected patients in whom the condition had been diagnosed by pneumoencephalogram.

The authors were unable to substantiate by roentgenography the work of others regarding the differentiation of Pick's disease and Alzheimer's disease. The utility of reliance on the roentgen ray was further substantiated by the pathologic diagnosis established at autopsy. It was further found that the condition in 2 cases in the group belonged to neither of the diseases under discussion but had the roentgen appearance described by others as characteristic. The authors therefore concluded that air encephalography was of little value as a means of differentiation among the various members of the presenile group but was very valuable as a means of separating the degenerative presenile cases from those with other conditions.

HORACE G. BUTLER, M.D.

Pantopaque Myelography in the Diagnosis of the Arnold-Chiari Malformation. BERNARD S. EATKIN. *Am. J. Roentg.* 1948, 59 339

This article deals with the report of a case of Arnold-Chiari malformation without associated skeletal or central nervous system defects, a review of previously reported cases and a discussion of the findings in this condition by pantopaque myelography.

The author states that the case presented is the fourth such case to be reported. The patient was a female 30 years of age who complained of pain and abnormal sensations in her left shoulder with radiation to the hand. Examination and study in-

duced a lesion in the upper cervical cord. Myelography was interpreted as indicative of an intrinsic lesion probably an extramedullary tumor. Operation revealed an Arnold-Chiari malformation with out skeletal or brain defects.

The myelographic findings described by the author as characteristic of this deformity consist of (a) in the direct anteroposterior projection of the head a bilateral concavity of the oil in the cisterna magna, and interpeduncularis separated by a column of oil in the midline and (b) the configuration of the oil seen in the cisterna magna with the patient's head turned to the right or left was a slight cephalad convexity whereas normally it is concave caudad following the normal contour.

The symptomatology of the condition in this and the previously reported cases is stated to be rather bizarre, cerebellar tumor being the most frequent preoperative diagnosis.

The myelographic findings described correspond with those reported previously as quoted by the author. Correlation of the findings with the illustrations was not entirely satisfactory. However as the author suggests the procedure of myelography in such cases may have definite application in the clinical investigation.

PAUL R. NOBLE, M.D.

Thoracic Aortography. B. BRODÉN, H. E. HANSON and J. KARNELL. *Acta radiol.*, Stockholm, 1948 29 181

A method of thoracic aortography through the introduction of a heart-catheter (8-gF) into one of the radial arteries after exposure in the fossa cubiti is described. Preliminary sedation and a local anesthetic are used. A compression device is placed over the abdomen to compress the abdominal aorta and delay the transport of the contrast substance from the thoracic aorta. The opposite arm is equipped with a pressure cuff filled above the systolic pressure. Fifty cubic centimeters of a 70 per cent solution of diodrast are injected with an ordinary syringe as fast as possible. Roentgenograms are made in two perpendicular directions simultaneously and at a speed of one pair per second.

This study has been carried out on 3 patients suspected of having a coarctation of the aorta or patent duct of Botallio. In the first patient, previous heart catheterization with gas analysis suggested the diagnosis of a patent duct of Botallio but no murmur could be heard or recorded which made the diagnosis uncertain. Subsequent thoracic aortography showed no evidence of a communication between the aorta and the pulmonary artery. A coarctation of the aorta was demonstrated in the second patient and a coarctation of the aorta with an associated patent duct of Botallio was found in the third patient.

Brief case reports on these three patients, together with the roentgenograms are included in this report. The results were so satisfactory that the authors plan to use this method instead of angiocardiology for contrast roentgenography of vascular malformations in the aorta and its intrathoracic branches.

JOHN H. FRED, M.D.

Radiographic Studies in the Roentgenologic Exploration of the Respiratory System (*L'indagine radiografica nell'esplorazione radiologica dell'apparato respiratorio*) LUIGI CASTALDI. *Radiol. med.* Milano, 1948, 34, 65

Röntgenography and roentgenography supplement one another and neither can be spared. The former method has the advantage of showing the different phases of a lesion as viewed directly on the fluoroscopic screen but has at the same time the disadvantage of failing to demonstrate details the latter method has, on the contrary the advantage of showing details but lacks in mobility. The method of roentgenography in series was designed by Busi in 1913 to remedy these defects.

The type of apparatus which is employed for this purpose consists essentially of a plate opaque to the roentgen rays in which is left an opening, a window measuring 9 by 12 cm. In this opening is fitted a fluorescent screen. To this plate is attached a mechanism consisting of a cassette (chamais) containing the roentgenographic film. By this mechanism the film can be moved in front of the opening in the plate and then shifted in different directions, with the result that 4 different views of the part under examination can be photographed. The process to be filmed is watched on the fluorescent screen until the particular phase to be fixed on the film is observed.

This method has previously been used almost exclusively in the study of the gastroduodenal tract (duodenum). The author now proposes that it be employed in the study of lesions of the respiratory apparatus. By this means the number and extent of the pleural adhesions in the process of pneumothorax during the operation of pneumothorax (J. cobacous operation) may be demonstrated. Images, which by the standard method of roentgenography might be interpreted as pulmonary cavities (pseudocavities) or as solitary or nodular tuberculous, may be clarified as to their true nature. The difference between the pulmonary cavity and bronchiectatic dilatations may be demonstrated especially with the aid of insufflation of iodized oil. Finally the steps of the treatment of the pulmonary cavity by the method of intracavitary aspiration, as used by the author's chief V. Monaldi, may be observed.

JOHN W. BRECKMAN, M.D.

The Roentgen Examination of the Mediastinal Lung Hernia with Reference to Tomography ILARIO SALIMON. *Ida. radiol.* Stockholm, 1948, 29, 30.

The author states that in this article the term of "hernia" is used with full recognition of the fact that there is a difference of opinion as to whether one is dealing with a true herniation or a local displacement of the mediastinum only.

There are two types of mediastinal hernia: one is caused by pulsion, as for example in pneumothorax, and the other is caused by traction due to diminished pressure certain anatomic conditions, leading to cir-

cumscribed resilient areas in the mediastinum, are the contributory factors. Nitsch described two such resilient areas: the first behind the manubrium sterni at the level of the insertion of the first to third ribs and the second in the lower posterior mediastinum at the level of the fifth to eleventh dorsal vertebrae. Bárány and Ward described a third weak place between the spinal column and esophagus at the level of the third to fifth dorsal vertebrae.

The pulson hernia is well demonstrated fluoroscopically. A sharply defined translucent area appears during expiration within the normal lung near the mediastinum at the level of the anterior ends of the first to third ribs. During inspiration the area gradually diminishes in size or disappears totally. This area corresponds to an air filled pouch of the opposite pleura.

The traction hernia is comparatively rare although Maye of the University of Michigan, described 30 cases. The author himself saw 6 cases in short time. The condition usually is the result of a shrinking of the lung (tuberculosis, bronchiectasis) or of chronic bronchoconstrictor (tumor foreign body) Lobectomy and pleural adhesions may enhance the formation of a traction hernia.

The roentgen diagnosis of traction hernia is based on a careful observation of the translucent area. In case of shifting of the mediastinum due to contraction of the hemithorax one should always search for a traction hernia. In the routine roentgenograms the hernia is often overlooked. An exposure with more penetrating roentgen rays is necessary to bring out the details to better advantage. Then the area is seen paramediastinally on the opaque side outlined by a horizontal upper border which crosses the mediastinum at the level of the sternoclavicular joint and turns downward laterally. The lateral border changes with the size of the hernia.

However often not even the more penetrating exposure is sufficient to demonstrate the traction hernia. Stereoscopic films roentgenograms taken in a lateral or oblique view and bronchograms are of little additional value. In such instances tomography may be of considerable help by visualizing the changed position of the pulmonary vessels in the area under question. Normally, the blood vessels are shown best in the tomographic layers of 9 to 1 cm., whereas in herniation they appear the clearest in the layers of 12 to 14 cm. This occurred in 5 of 6 of the author's cases.

The 6 cases are briefly described and the respective roentgenograms and some diagrams are used for the purpose of illustration. The cause of the mediastinal hernia was given as pneumothorax in 1 case, lobectomy in 1 case shrinking after discontinuation of pneumothorax in 3 cases, and pleural adhesions in 1 case. In all 6 cases, part of the healthy upper lobe of the lung herniated into the diseased side through the weak spot of the upper anterior mediastinum. In one case there was also overlapping in the region of the lower posterior resilient area.

T. LECHE, M.D.

Early Pleural Effusion in Pulmonary Embolism and Pneumonia or Bronchopneumonia GUMMAR
MORBERG *Acta radiol. Stockh.*, 1948 29 7

The roentgen diagnosis of pulmonary embolism has previously been based on the demonstration of the characteristic triangular infarct shadow with its base facing the pleura and the apex pointing toward the hilus. In order that the infarct should appear as a triangular shadow on the roentgenogram, however it would be necessary for the roentgen rays to strike the triangle from the side at an angle which does not diverge too much from 90 degrees. Otherwise an uncharacteristic shadow would be obtained. Recently it has been proved that the wedge-shaped shadow with its apex toward the hilus is not characteristic of a pulmonary infarct. Pulmonary embolism may often occur without any demonstrable density in the parenchyma of the lung.

Pulmonary embolism usually leads to changes in the pleura. There is a frequent relationship between pleural effusion and infarction. To estimate the significance of early pleural effusion in pulmonary embolism the author has studied the findings in 46 patients with pulmonary embolism roentgenographed within 3 days of the appearance of symptoms, and 38 patients with pneumonia or bronchopneumonia examined within 6 days of the onset to determine the significance of an early pleural effusion from the differential diagnostic standpoint. In about half of the cases of pulmonary embolism the pleural effusion dominated over the parenchymal density while in a little less than half the reverse was true. In 2 of the 38 cases of pneumonia and bronchopneumonia the pleural effusion dominated and in 3 cases the pleural effusion and the parenchymal density were equally dominant. All of the 5 patients were examined within 3 days of the first symptom. In the 33 other patients 18 of whom were examined within 3 days the parenchymal density was the dominating roentgen finding. It can be said that an early pleural effusion when there are no or only small, parenchymal densities is common in postoperative pulmonary embolism but less common in a medical series of pneumonia or bronchopneumonia cases. In a considerable proportion of cases of pulmonary embolism large parenchymal densities occur without demonstrable pleural effusion or with only slight pleural effusion.

FRANK L. HICKEY, M.D.

Accidental Extrapleural Pneumothorax OLLE OLSSON
Acta radiol. Stockh., 1948 29 117

While performing an artificial pneumothorax for collapse therapy the parietal pleura may be stripped from the chest wall and smaller or larger quantities of gas deposited extrapleurally.

After a brief review of the literature the author reports 7 cases of accidental extrapleural pneumothorax which he observed during the past 2 years. The case histories are briefly given emphasis being laid on the roentgen findings. The respective roentgenograms and one diagram are used for the purpose of illustration.

The anatomic background of an extrapleural pneumothorax is explained as follows.

The thoracic cavity is lined first with the endothoracic fascia which is firmly attached to the periosteum of the ribs and the aponeuroses of the intercostal muscles then with the parietal pleura which can be separated from the fascia over almost its entire extent along the chest wall. By using a coarse blunt needle or a needle with a long opening one may easily strip off the parietal pleura instead of going through it and thus an accidental extrapleural pneumothorax is produced. A warning sign is that in such an instance the pressure rises rapidly during the course of the injection of the gas although this was not observed in the author's cases.

The most important roentgen findings are a column shaped collection of gas when the pleura is separated from the chest wall over a large extent or a cyst shaped area when the detachment of the pleura is limited. In contradistinction to the ordinary pneumothorax which is delineated by a membrane hardly a millimeter thick the extrapleural pneumothorax represents an entirely free space the size of which varies greatly from case to case and depends on the amount of gas deposited extrapleurally. Another distinguishing feature is the fact that an extrapleural pneumothorax takes a very long time to absorb. In one case the gas was still present after 2 years.

Accidental extrapleural pneumothorax is not uncommon. However it is recognized in the majority of cases only if it is especially looked for. Its clinical significance lies in the fact that (1) it may produce pain in the hypochondrium and a "tight feeling" in the chest (2) it may lead to confusion with adhesions, in which case the collapse therapy is unnecessarily discontinued (3) the increased manometric pressure may appear puzzling and induce abandonment of collapse therapy and (4) the extrapleural deposit of gas brings the two pleural sheaths closer to one another facilitating the formation of adhesions especially in the later stages because of the further absorption of the gas in the intrapleural cavity. The latter phenomenon may eventually lead to a gradual reduction and complete destruction of the pneumothorax cavity on subsequent refills.

T. LECUTIA, M.D.

Alterations of the Thoracic Bones in the Diagnosis of Pulmonary Tumors (Le alterazioni dello scheletro toracico nella diagnosi dei tumori polmonari)
GIORGIO GAROZZA *Radiol. med. Milano* 1948 34 146

Up to the present time little attention has been paid to the lesions of the thoracic bones in cases of pulmonary tumor and yet they are often very important from the diagnostic point of view. They may be due to spread of the tumor to the bone or to compression of the bone by the tumor. The first type is more frequent than the second and may be due to metastasis or to spread by contiguity.

In a study of 40 cases of primary tumor of the lung the author found bone changes in 10 or 25 per

cent. The most frequent changes were those which belong to the Pancoast syndrome (osteolytic changes of one or more ribs in their posterior portion and sometimes also of the corresponding vertebrae) other changes consisted of osteolytic patches in segments of the ribs or of the clavicle sometimes large and sometimes so small that they easily escaped observation. Often the massive opacity of the pulmonary tumor or of the relative atelectasis was the reason why these lesions especially when they were small, were easily overlooked. Therefore the author finds it advisable to call attention to the necessity of studying the thoracic cage every time the suspicion arises that a pulmonary infiltration might be due to a neoplasm. In these cases films should be taken with appropriately hard rays in the various positions which allow observation of all the bone segments of the chest and the tomographic method may offer decided advantages.

The bone changes generally present the following characteristics: more or less irregular reduction in size and zones of decalcification of trabecular aspect with large openings delimited by thinner and often incomplete trabeculae. In the course of time, the roentgen picture becomes worse and pathologic fractures may occur or segments of the rib may become cancellous and even the entire rib may disappear. When several ribs are involved the changes always occur at least partially in the same segment although some ribs may be in a worse condition than others or be more extensively involved. If there is only decalcification, restitution with recalcification is possible in conditions which respond to roentgen therapy.

Sometimes the bone lesions are mistaken for tuberculous processes or primary bone tumors. Also a benign tumor or an aneurysm by pressure on a bone may cause loss of substance and thus be a source of error but the loss will be well delimited and circumscribed and without decalcification at a distance.

The presence of pulmonary tumor may also give rise to remote bone lesions of metastatic type or of another type of which the pathogenesis is not yet clarified but is generally believed to be of toxic dystrophic character i.e. the syndrome of hypertrophy and pneumonic osteopathy of Pierre-Marie.

RICHARD KEMMEL, M.D.

On the Pathology and Roentgen Diagnosis of the Apical Cancers and the Malignant Periapical Tumors (Sur la pathologie et le diagnostic radiologique d' cancer apical pulmonaires et des tumeurs malignes péri-apicales). R. MATHY-CORMAX and DE FLEURIAN. *Acta radiol.*, Stockholm, 1938, 29: 9.

The authors give a brief historical review of apical cancer since the original description by Pancoast in 1924 and the description of the Claude-Bernard-Horner syndrome by the French in 1928. Since this time many other cases have been reported. Especially of interest is the thesis of Tobias. The authors themselves have encountered 93 cases, and their observations are as follows:

Men are affected in from 85 to 90 per cent of the cases and the maximal age incidence is from 40 to 55 years. In women the disease often is found to be a metastatic lesion. The syndrome may be complete or incomplete according to the anatomical organ from which the tumor arises. In order to be complete the pulmonary apex (roentgenological shadow) and the periapical and supra-apical regions (neurological signs) should be invaded. Furthermore, the tumor can be of various histological natures as well as in various sites. Histologically it may be an epithelioma or adenocarcinoma if it has originated from a bronchiole. The periapical tumor may be a pleural endothelioma, sympathoblastoma, thymoma, or bronchioma, arising from the embryonal tissues. The metastatic tumors of the apical and supra-apical regions are mostly from carcinomas of the breast, stomach and cervix uteri, from sarcomas, hypernephromas, or teratomas of the testis. Other tumors such as neurinomas and lymphomas and Hodgkin's disease have been reported.

The diagnosis is not always easy especially when the syndrome is incomplete. In the beginning the roentgenological finding may be represented by a very limited horn or semilunar shadow. This shadow is homogeneous, leaning against the posterior arch of the first and sometimes of the second rib, continuing medially toward the corresponding articulation between the rib and the transverse process of the vertebra exteriorly to the upper border of the clavicle. It is at this stage that one has to keep in mind the possibility of apical tumor and not to be satisfied with a simple diagnosis of arthritis, apical pleuritis, or neuralgia. The authors state that there were cases considered as apical pleuritis which turned out finally to be malignancies. The tumor is spherical or ovoid in shape surrounded by a zone of atelectasis with sometimes many indentations in the form of crab's paws. However in the majority of cases, the tumor is discovered often after a certain period of involution. It then appears as a mass shadow in the apical area, contiguous to the spine. Tomography should be used to determine the extent of the lesions. High myelography is of help to see whether or not there is involvement of the spine. Bronchography is difficult in the study of this area. In certain rare cases however a bronchogenic tumor has been discovered. Pneumothorax is always difficult to perform because of the presence of pachypleuritis and adhesions.

The authors then describe the special radiological projections they used in the examination of this area. No special scheme is presented concerning the projections used. Biopsy has not been mentioned.

As far as treatment is concerned both surgery and radiotherapy have given poor results. Surgical results may be satisfactory in certain well localized and early diagnosed cases. Radiotherapy has shortened the life of the patient in certain cases. Novocain injection into the brachial plexus is insufficient to stop the pain. Radicotomy or cordotomy must be done.

A few roentgenograms and a brief bibliography are presented.

MARC K. P. SIE, M.D.

Röntgenological Heart Volume Determination with Special Regard to Pulse Rate and the Position of the Body HARRY LARSSON and SVEN ROLAND KJELLBERG. *Acta radiol.*, Stockh. 1948 19 159

The authors describe 4 different methods for determination of the heart volume. For practical purposes they use the Rohrer Kahlstorf formula $V = S_1 \times d \times k$ in which S_1 is the PA surface area of the heart in the lateral view and d is the largest depth posed to be constant however the authors showed that it is not constant and varies from case to case with the heart's shape and tilt. When the heart has the appearance of an ellipsoid the volume is calculated as follows $V = d_1 \times d_2 \times d_3 \times k$, where d_1 and d_2 are respectively the long and short diameters and d_3 the depth the factor k must be determined in each case. The authors have shown how this factor is determined. In general a heart which is nearly spherical has a low factor while one which is flatter has a high one.

In order to avoid the volume diminution due to the hydrostatic blood displacement in the standing position the authors make their determinations with the patient in a prone position. The PA and lateral radiographs are taken with the shortest exposure time and this is done through an electrocardiographic apparatus with an attachment coupled to a built-in relay which gives an exposure at any desired point in the heart cycle. The exposure is performed in maximum diastole just before the R wave since the heart movement is slow and insignificant at this time and the sharpness of the heart image is maximal. However in the investigation of mitral lesions the exposure should be made at the end of systole at the time of the T wave. An electrocardiogram is taken at the same time as the exposure and the pulse rate is obtained. The authors give a simple method of correcting the heart's magnification.

In this investigation it has been established that in the lying position the heart's volume undergoes no demonstrable change with pulse increases up to 120/min. On the other hand in the upright position a diminution in heart volume proportional to the elevated pulse rate takes place. The pulse rate must rise from about 75 to 80/min. before any volume decrease can be observed. The difference in volume between lying and standing positions is not proportional to the difference between the pulse rate in the respective positions but to the difference in the registered pulse rate. In the sitting position a successive decrease in heart size takes place with the progressive rise in the pulse rate by virtue of hydrostatic blood displacement. The greatest decrease was as high as about 16 per cent and occurred with a pulse rate of about 120/min. This value is exactly the same as that obtained by Hodges and Eyster in their investigation. The authors were unable to confirm the large volume difference up to 40 per cent between the lying and upright positions as found by Nelin.

JOACE DE LA FLOK M D

Experimental Studies on the Motility of the Gastric Mucosa in Dogs. FRANK P. BROOKS, LLOYD W. STEVENS, EUGENE P. PENDERGRASS, and FRANCISCO BASSOLA. *Am J Roentg* 1948 59 482

The authors have observed the movements of the muscularis mucosae and of the muscularis propria in the living dog by means of roentgenoscopic and roentgenographic studies. The method consisted of anuring six lead shot through the serosa to the greater curvature of the stomach.

Several months previously 7 c.c. of colloidal thorium dioxide had been injected into the submucosa of the anterior wall of the stomach about 10 cm from the pylorus 6 c.c. about 6 cm from the pylorus near the greater curvature 10 c.c. about 3 cm from the pylorus near the greater curvature and about 3 c.c. in the anterior wall of the first portion of the duodenum. Roentgenographic studies showed that the thorotrast had spread out through the stomach wall which permitted a very satisfactory visualization of the mucosal folds of the stomach.

The best results were obtained in the actual study of the stomach by passing a modified Miller Abbott tube into the dog's stomach and inflating the balloon with 30 c.c. of air. The tube was then pulled out as far as possible in order to block off the cardiac opening of the stomach. Fifty cubic centimeters of water were then injected through the tube, followed by 100 c.c. of air and the tube was clamped. Roentgenograms were made at one-half or one-minute intervals. With such a technique definite changes were demonstrated in the form of given mucosal folds during a period in which the position of the shot remained relatively constant. This was interpreted as evidence that the mucosa possesses the ability to move, due to contractions of the muscularis mucosae independently of the muscularis propria. Similar roentgenograms were made after the subcutaneous injection of mechoyl which demonstrated movement of both the muscularis propria and the mucosal folds.

The authors conclude that the gastric mucosa is capable of movement due to contraction of the muscularis mucosae independently of the muscularis propria.

FRANK L. HUSKEY M D

On Roentgenological Diagnosis of Jejunitis Acuta Phlegmonosa "O W. HUSEBYE. *Acta radiol.*, Stockh., 1948, 19 71

The author describes the roentgen recognition of an acute inflammatory process in the jejunum characterized by tissue destruction, abscess formation and possibly gangrene of a segment of bowel. The clinical symptoms may be severe abdominal pain (either general or localized in the epigastrium) vomiting intestinal bleeding and fever. It is thought that some patients recover spontaneously while those whose condition is severe enough to be recognized may require surgery and infectious medical therapy or both. Among 14 cases observed in a 3 year period a tissue diagnosis was made in 6. Five cases are described in some detail. In 2 of these 5

cases operation was done with confirmation of the preoperative roentgen diagnosis by subsequent pathological study of the tissue. Three patients were treated only medically and recovered.

The roentgen findings were stated to be as follows:

1. Reduced diaphragmatic motion on one or both sides.

2. Survey films showed two loops of moderately distended small bowel in the left upper quadrant. The outlines of these loops were roughly serrated and the loops seemed to be somewhat fixed in position and outline.

3. In some cases these loops of gut contained small fluid levels.

4. On barium suspension the involved loops showed a fixed mucous membrane pattern and the fixed position and contour as noted on the survey films was confirmed.

5. The large intestine contained more gas than usual.

6. Passage of the contrast meal through the small bowel was not delayed but the affected loops retained some barium long after the rest of the small intestine was empty.

7. In some cases signs characteristic of peritonitis occurred as complications of the condition developed.

PAUL W. ELLER, M.D.

Hysterosalpingograms in Genital Tuberculosis in Women WILHELM MADSEN *Acta radiol. Stockh.* 947:25:8

The aim of this article is to show which types of roentgenograms are obtained by hysterosalpingography on patients in whom the genital tuberculosis has been verified by laparotomy or endometrial biopsy. It also aims to show that with our present knowledge concerning the interpretation of the roentgenograms obtained hysterosalpingography has revealed the presence of genital tuberculosis in a number of women whose symptoms were vague and by no means suggestive of tuberculosis. Often the only complaint of the patient was her sterility. In some of the cases ordinary gynecological examination had shown no abnormality.

The author emphasizes that even though there is probably no absolutely specific roentgenographic appearance for tuberculous salpingitis, the following features are strongly indicative of the tuberculous nature of the lesion: (1) when the abdominal ostium is closed, the tube is often considerably less dilated than in other etiological forms of salpingitis (dilated tube with retention of secretions); (2) areas of calcification are sometimes seen in the tube, and (3) calcified glands are sometimes seen in the pelvis.

The observation is made that retention of the contrast medium in tubes which are dilated but slightly or not at all, is highly suggestive of a tuberculous origin of the salpingitis, whereas retention in dilated tubes is the most frequent form of salpingitis when the salpingitis is of gonorrheal or septic origin.

The article includes illustrations and text descriptions of the fractures encountered in 4 patients

with histologically verified genital tuberculosis (20 patients) or with nonhistologically verified, but otherwise highly probable, genital tuberculosis (22 cases). The author believes that the procedure had been of considerable significance both with regard to the establishment of the presence of an inflammatory process in the genitalia and also with regard to calling attention to the circumstance that the inflammatory process might be tuberculous.

MARILYN W. MILLER, M.D.

Further Experiences in the Roentgen Diagnosis of Tuberculous Salpingitis. W. MAGNUSSON. *Acta radiol. Stockh.* 947:28:234.

Hysterosalpingography has acquired increasing importance in the analysis of the causes of female sterility. In spite of the large and widespread experience with this type of examination, it has hitherto been used almost exclusively for investigating the patency of the fallopian tubes and very little interest has been devoted to the study of the roentgenographic appearance of the tubes themselves after different types of salpingitis.

In a previous study of salpingograms in 22 cases of tuberculous salpingitis verified histologically the author found that finely jagged and ragged contours with small lumen defects, and sometimes with abscess and fistula-like extensions of the tubal lumen constituted the roentgenological signs of tuberculosis. The anatomical basis for the changes is probably the swollen and tightly folded mucous membrane.

On the basis of further experiences in 7 new cases and following a re-examination of all cases with tubal occlusion, a second type of salpingographic picture in tuberculous salpingitis is described. It is characterized by straight and rigid contours of the lumen and often by pipelike configuration of the tube. As the result of these examinations it is concluded that a preoperative diagnosis of tuberculous salpingitis is possible in most cases when tuberculosis is the cause.

MARILYN W. MILLER, M.D.

On the Technique of Lumbar Pneumomylography OLUF OLSSON. *Acta radiol. Stockh.* 948:49:97

Experience shows that prolapsed discs, especially in the region of the lower lumbar spine, can often be demonstrated only by means of myelography. Both positive and negative contrast media may be used. The author gives a brief review of these media.

The negative media, among which sterile oxygen is the most important, have three disadvantages: (1) the slight contrast, (2) the long time required for the examination and (3) the ill effects after the examination.

In the present article the author describes a simple technique, aiming to eliminate the three disadvantages. This technique in fact, is a modification of that of Busch and Lindgren. It is as follows:

The lumbar puncture and withdrawal of cerebrospinal fluid are done with the patient lying on a stretcher horizontally on his side. Then one end of the stretcher is lifted, the gas is injected, and the

roentgenograms are taken with the aid of crossed Lysholm grids which are placed upright against the back of the patient. The gas is injected with the Lindgren apparatus a pressure of from 300 to 400 mm of water being maintained. The roentgen rays are directed horizontally. The roentgenograms are made in the straight lateral position as well as with the upper part of the patient's body angulated back at various degrees. The crossed grids mean that two ordinary Lysholm grids are placed at right angles to one another. Such a procedure has the advantage that the irregular structure of the vertebral bodies is replaced to a large extent by a regular network from the grids against which the gas can easily be seen.

The method also permits the visualization of the root pockets and in many instances of the roots themselves. The patients show practically no ill effects because of the swiftness of the examination and the rather low pressure used.

The stretcher procedure is illustrated by photographs and 2 sets of roentgenographic reproductions are included.

T. LEUCUTIA, M.D.

The Roentgen Picture of Osteoarthritis in the Hip Joint in Cases of Polyarthritidis Rheumatica Chronica. IVAN HERNIMONSON. *Acta radiol* Stockh., 1943, 29, 139.

The author has studied a number of cases of arthritis of the hip and has attempted to group and classify these according to the various roentgen findings. To fully understand the discussion it would be necessary for the reader to be familiar with the author's previous work on related subjects. The roentgenographic means clearly stated one can by the principal conclusion is clearly stated one can by the roentgenographic means differentially diagnose arthritides of the hip and osteoarthritis when the hip is normally developed. In maldeveloped hip joints this differentiation is not possible.

PAUL W. LYLE, M.D.

Ossifying Hematomas and Other Simple Lesions Mistaken for Sarcomas. JAMES F. BRADFORD. *Brit J Rad* 1943, 21, 157.

Because the author was repeatedly faced with bone lesions the treatment of which had been based on the erroneous findings resulting from biopsy he endorses what Fung said namely that "the whole clinical and radiographical picture of the case of bone sarcoma usually furnishes a better conception of the diagnostic and therapeutic problem than can be obtained from a biopsy." In the present article the author gives several examples to illustrate this point.

In Case 1 a young woman aged 20 the original roentgen diagnosis was that of a chondrosarcoma of relatively slow growth of the lower third of the femoral shaft. However a subsequent biopsy revealed negative for evidence of malignancy. Final diagnosis of chondrosarcoma was sustained also histologically and at amputation at the right hip joint.

Case 2 that of a girl 5 years of age represents an osteogenesis imperfecta in which multiple hemorrhages led to large calcified hematomas representing tumors. In particular the shafts of the humeri and femora were enveloped by massive calcareous deposits eventually leading to absorption of the shafts of the shafts involved. An erroneous diagnosis of multiple exostoses was made. There was no malignant metastasis in this case. However to prove the fact that such ossifying hematomas can be interpreted as sarcomas on clinical histological and radiographic evidence the author cites 2 other cases.

In Case 3 that of a child 3 months old a diagnosis of osteogenic sarcoma of the femoral shaft was made but subsequent roentgen studies established the presence of an ossifying hematoma which later absorbed the femur becoming of normal appearance. The other case which is not described in the text was that of a surgeon's little daughter. The nurse discovered on the child's arm a mass associated with a bone which was tender on pressure. Originally a diagnosis of sarcoma was made, but after a more thorough roentgen study the benign nature of the lesion was established and no amputation was performed.

Additional samples of ossifying hematomas are the large hemorrhages which occur in limbs in which the nerve supply has been damaged in hemophilia. Charcot's joint spina bifida apparently without any known trauma congenital syphilis intramedullary infarcts of caisson workers and the so-called osteoid osteoma. A differentiation in all these instances from a possible malignant tumor of the bone is very important.

The author includes many roentgenographic reproductions for the purpose of illustration some of which are quite unusual.

T. LEUCUTIA, M.D.

Practical Aspects of the Diagnosis, Treatment and Prognosis of Hodgkin's Disease and Allied Disorders. HENRY JACKSON JR. *Radiology* 1943, 50, 481.

The author divides Hodgkin's disease into 3 types the comparatively benign paraneoplasia the more frequent and more fatal granuloma and the rare but extremely malignant sarcomatous type. Lymphosarcoma and reticulum cell sarcoma are also discussed.

The author states that Hodgkin's granuloma is encountered most often and he believes that for about every 250 cases of Hodgkin's granuloma there will be 100 cases of reticulum cell sarcoma 60 cases of lymphosarcoma and perhaps 50 cases each of Hodgkin's paraneoplasia and Hodgkin's sarcoma.

Symptoms are discussed briefly and the protean character of the symptomatology is pointed out. The therapeutic approach to the various types of Hodgkin's disease is different. In the authors opinion Hodgkin's paraneoplasia if sharply localized to one area should be excised and thereafter moderate doses of radiation given in the involved area. If it is generalized moderate doses of roentgen irradiation

radiation are considered sufficient. Likewise, in Hodgkin's granuloma if the disease is sharply circumscribed and accessible and there are no general symptoms such as fever or anemia, the author advises radical excision followed by irradiation. If it is generalized when first seen as this type usually is, the author administers only moderate amounts of roentgen irradiation to the involved areas. Heavy doses are not advocated, but it is suggested that therapy be continued until it is clear that further treatment can do no good.

If Hodgkin's sarcoma, the author recommends that the best treatment is to keep the patient comfortable. In cases of lymphosarcoma, if it is localized as rarely is, excision may give a good result. If it is inoperable radiation is all that is offered. If reticulum cell sarcoma is localized and accessible, the author believes that excision should be done. If the disease is localized but not operable heavy irradiation is recommended if it is generalized sufficient roentgen irradiation to alleviate symptoms is all that is indicated. *Barn to C. Ruyter, M.D.*

Experimental Studies on the Toxicity of Priodax. *John Howard Am. J. Roentg. 94:3, 59 408.*

Tetralodophenolphthalein a drug widely used in cholecystography is excreted largely by the liver and partly by the kidneys. Dick and Wallace in 1928 experimentally studied its effect on the pancreas and they arrived at the conclusion that there is risk of damage to the pancreas in jaundiced patients who are afflicted with chronic obstructive lesions of the biliary tract. This explains why tetralodophenolphthalein is not used for cholecystography in the presence of obstruction to the extrahepatic biliary tract or in suspected pancreatitis.

In 1940 priodax, which contains 51.5 per cent iodine by weight, was introduced and since then has found extensive clinical application.

The author in a series of experiments performed on cats and dogs, determined the effects of the priodax on pancreatic tissue.

The effects of priodax on the pancreas under normal conditions. Four normal dogs and 3 normal cats were used. The priodax was given by mouth in doses of from 400 to 500 mgm. per kilogram of body weight to dogs, and of approximately 250 mgm. per kilogram of body weight to cats. After 24 hours a laparotomy was done the pancreas was studied grossly and in 3 days also microscopically and the iodine concentration in the gall bladder bile was determined. No damage was noted.

The effects were also studied clinically on 9 normal patients by means of serum amylase determinations. A dose of 3.0 grams of priodax was given orally. The gall bladder was visualized roentgenographically in each instance. There was no pancreatic damage.

The effects of priodax on the pancreas in case of obstruction of the common bile duct. For this experiment 6 dogs and 3 cats were used. Under sterile conditions the common bile duct was doubly ligated and 18 hours later a second laparotomy was done. 7 days

after the administration of the drug. The pancreas was examined grossly and histologically and the iodine concentration of the bile aspirated from the gall bladder was determined. Four of the dogs were sacrificed on the seventh day and the pancreas was re-examined. Except for two minor changes incidental to technique, the pancreas appeared normal.

The effects of priodax suspended in physiological saline solution when injected into the pancreatic duct. Seven dogs and 4 cats were used. The major pancreatic duct was exposed by blunt dissection and ligated at its entrance into the duodenum. In the dogs from 0.8 to 4.3 mgm. of priodax, and in the cats from 0.6 to 0.75 mgm. of the dye (a suspension of 500 mgm. of priodax in 100 c.c. of physiological saline solution) was injected into the pancreatic duct. Of the 7 dogs, only one showed evidence of injury consisting of fat necrosis with death. The pancreas of the cats showed a slight localized edema or fat necrosis at the site of the ligation. A similar change however was observed also in control animals in which only physiological saline solution was injected into the main pancreatic duct.

Injection of gall bladder bile contains no priodax into the pancreatic ducts. In this additional experiment 4 dogs and 3 cats were used. The dogs were given 3 grams of the priodax orally. After 24 hours bile was withdrawn from the gall bladder and 1 c.c. was injected slowly into the pancreatic duct as in the previous experiments. Biopsy of the pancreas was then done from 24 to 72 hours later. In the cats 500 mgm. of priodax were given orally and 24 hours later 0.5 c.c. of gall bladder bile was injected into the pancreatic duct. In practically every case marked injury of the pancreas developed consisting of edema, edema, and fat necrosis. In a control group of animals in which 0.5 c.c. of bile without priodax was injected into the pancreatic duct the same widespread changes occurred.

The results of these experiments indicate that in unobstructed biliary tracts no damage to the pancreatic tissue is produced by the priodax. Likewise there was no evidence that in the presence of acute extrahepatic biliary obstruction injury is attributable to the priodax. Bile injected into a pancreatic duct of the dog produced such injury to the pancreas that the added effect of the dye in the bile if any could not be properly evaluated. *T. LECOTTE, M.D.*

Morphologic and Functional Damage in the Region of the Extremities as a Result of Previous Arteriography with Thorotrast (Morphologische und funktionelle Schädigungen im Bereich der Extremitäten als Folgen vorangegangener Arteriographie mit Thorotrast) Otto Stank. *Heid. chir. wch.* 94:7 4 400.

A description of the pathologic findings in 4 cases of obliterating arteritis in which arteriography of the lower extremities had been carried out with thorotrast is presented. There were 3 cases of arterioendarteritis and one case of Buerger's disease. Observations were based on local and microscopic studies, on

roentgenograms and general postmortem findings. It is generally assumed that the intravenous injection of a maximum of 20 c.c. of thorotrast is followed by a rapid thinning and dilution of the material and an insignificant diffuse storage in the reticuloendothelial system after passage through the first capillary bed.

The author states that these assumptions are false. In the reported cases of obliterating arteritis, numerous thorotrast emboli were observed in the arterioles and capillaries and in the surrounding connective and fat tissues. Degenerative changes in the vessel walls involving the endothelium, media, and adventitia with perivascular hemorrhagic edema and ischemic necrosis were observed. These changes are attributed to local anoxemia resulting from embolic obliteration and injury to the vessels rather than to any physical or chemical reaction to the thorotrast. There was also evidence that the damaged vessel walls permitted the oozing through of quantities of thorotrast in the first capillary net to establish thorotrast depots. The extravascular thorotrast is removed only to a slight extent by the lymph and remains to cause constricting scar tissue formation and later damage to the vessels and nerves. In 2 cases a fatal, toxic anemia followed the injection of thorotrast. The clinical course resembled that described for the crush syndrome and was attributed to the occurrence of muscle ischemia following the injection of thorotrast.

The use of thorotrast for arteriography is condemned as too dangerous especially since new, molecularly dissolved radioopaque substances which appear to be harmless are available.

JOHN L. LIXOQUER, M.D.

The Presentation and Analysis of the Results of Radiotherapy J. W. BOAG, *Brit J Radiol* 1948, 21: 128.

Analysis of the results of radiotherapy in the treatment of carcinoma has never been entirely acceptable to those concerned with cancer treatment. Many difficulties are encountered viz., death of the patient as a result of intercurrent disease, small group of cases and incomplete use of history and information.

A method has been devised whereby full advantage may be taken of all patient information. This is especially important in attempting to evaluate the results in a recently treated patient, or in one who was treated many years ago or who died of intercurrent disease.

A dot diagram method was used wherein each dot represents a patient. Four forms of dots were used to indicate whether the patient died with cancer or from intercurrent disease or whether the patient is alive and symptom free or alive but with evidence of cancer. The position of the dot on the time scale indicates the time that elapsed between the beginning of treatment until death of the patient or until the analysis was made. The dots can be made to render information such as whether the

patient died with the disease in the primary site or in metastatic glands. Care should be taken to avoid making the chart top-heavy with different types of dots.

Many instructive graphs (a series of carcinoma of the tonsil and mouth) are shown to illustrate how to obtain the most of the best instructive data from any given series of cancer patients.

MAURICE D. SACHS, M.D.

Histologic Changes in Squamous-Cell Carcinoma of the Mouth and Oropharynx Produced by Fractionated External Roentgen Irradiation JOHN W. HALL and MILTON FRIEDMAN, *Radiology* 1948 50: 318.

The authors studied the histologic effects of fractionated roentgen irradiation as used in the modern radiotherapeutic technique. The administration of roentgen rays in small daily fractions permits the normal epithelium to recover somewhat each day from the irradiation injury, but the less differentiated tumor cells for the most part show no evidence of recovery. Fractionation also increases the number of times each tumor cell is exposed to irradiation while in the premitotic or mitotic phase which is believed by many to be the most radiosensitive phase.

The material studied was obtained from 28 patients with squamous-cell carcinoma of the mouth and oropharynx who were subjected to periodic biopsies during treatment. Two techniques were used. Twenty-four of the patients were given a standard technique which consisted of the administration of a daily skin dose of 400 roentgens (with back scatter) to provide an approximate average daily tumor dose of 275. The total tumor dose averaged approximately 6,000 roentgens to 6,500 roentgens in from 23 to 28 days. Four patients were given one half of the daily dose of the standard technique which consisted of 200 roentgens (measured with back scatter) to provide approximately 135 roentgens daily to the tumor over a period approximately twice the length of time to approximate the dosage of the standard technique. The physical factors were 300 kv, 0.5 mm or 2.0 mm of copper filter, 30 ma, 50 cm. target-skin distance usually with a 10 by 15 portal, half value layer of 0.9 or 1.8 mm of copper, and a dosage rate of from 10 to 40 roentgens per minute. The biopsy material consisted of 140 specimens from 28 patients. Each patient except one had a pretreatment biopsy.

The histological changes produced in the tumor cells following irradiation of squamous-cell carcinoma were of the following major types: acute cell death, progressive enlargement of the cells to giant-sized tumor cells, and radiation keratogenesis. Various combinations of changes were noted in a single tumor undergoing destruction by radiation.

Acute cell death is the most common change. It affects the cytoplasm, nucleus and other components of a cell impartially and is usually seen in the first 7 days. This is the process whereby the most radio-

sensitive cells are destroyed. Its importance has not been sufficiently emphasized.

The less sensitive cells, not undergoing acute cell death, show progressive enlargement to giant-sized tumor cells. This is the result of two different mechanisms (1) swelling and vacuolation of the cytoplasm and to a lesser extent of the nucleus, probably through a physicochemical disturbance of the intercellular and intracellular exchange of fluids and (2) disruption of the nuclear function resulting in the formation of various nuclear abnormalities.

Radiation keratogenesis, another mechanism of cell destruction, is the acceleration either in time or degree of the normal process of keratinization. It is a cytoplasmic phenomenon.

Under-irradiation of a tumor (chiefly in the form of an inefficiently small daily dose) produces some destruction of tumor cells, but chiefly provokes maturation of the more radioresistant cells.

The most pronounced change in the stroma is replacement fibrosis secondary to and in proportion to radiation destruction of tumor. Irradiation also increases hyalinization of the connective-tissue stroma, and to a slight extent produces degenerative changes within some fibroblasts namely swelling and vacuolation.

With fractionated irradiation damage to the blood vessels is usually slight and occasionally moderate in degree.

A single biopsy taken between the seventh and eleventh days during a course of fractionated irradiation will yield considerable information concerning the radioresensitivity of the tumor and the effectiveness of the irradiation technique.

FRANK L. HOWARD, M.D.

An Anatomic Classification of Cancer of the Larynx for Use in Radiation Therapy. EDWARD L. JENNINGS and EVERETT L. PIERCE. *Am J Roent* 94:5, 59.

A new anatomic classification of laryngeal carcinoma is offered for use by radiologists. The authors believe that while the anatomic classification of intrinsic and extrinsic lesions is all-important to the laryngologist it is relatively unimportant to the radiologist since it is the extent, rather than the location of the lesion which is important in determining the prognosis. Intrinsic and extrinsic terminology is still used primarily for the benefit of the laryngologist. Lesions are classified according to stages, i.e. stage 1 is the involvement of any one area whether it be true or false cords; stage 2 is the involvement of any two adjacent areas; stage 3 is the involvement of any two nonadjacent areas or any three adjacent areas; and stage 4 is the involvement of more than three areas, the regional glands or distant metastasis. Before classifying the stage of the disease it is advisable to obtain biopsy by means of direct laryngoscopy as well as soft tissue films of the neck.

On the basis of the above classification, 58 patients were treated from 1936 to 1945. Of this number 4 were treated only once or twice and therefore are

not included in this statistical survey. Nine other cases were not adequately followed up so they too are not included. Therefore 45 cases are analyzed for statistical purposes.

The disease occurred mostly in the third decade of life. The over-all occurrence as to stages was as follows: stage 1, 5 cases; intrinsic, and 4, extrinsic. In this group 3 of the patients in the intrinsic group survived for 61.4 months, and 3 in the extrinsic group had an average survival of 45.3 months. Stage 2: 1 case intrinsic none alive; 1 case extrinsic with a survival rate of 28 months. Stage 3: 5 cases, intrinsic, with 26.2 months average survival; 4 patients alive; 2 cases, extrinsic, none alive with an average survival of 26 months. Stage 4: 6 cases, intrinsic, 2 alive with an average survival of 17.5 months; 2 cases, extrinsic, with an average survival of 13.1 months; 6 patients alive. The over-all average of all these cases was as follows: intrinsic group — 17 patients with an average survival of 34.6 months; 11 alive; extrinsic group — 28 patients with an average survival of 8.3 months; 10 alive.

Ten patients had to have tracheotomies while under observation. 6 of them before treatment and 4 after treatment was started. A gastrostomy was required in 3 other patients. A laryngectomy was required in 2 patients before treatment and in 1 after treatment. The latter 2 were operated on for probable local recurrence. Two patients had laryngeal fissures followed by recurrence for a short period, for which radiation was administered.

Technical factors consisted of 200 kv, 20 ma. tubeless filter 50 cm. target skin distance 10 cm. use field, directed to the larynx, a daily dose of 200 roentgens measured in air, total dose of 3,800 roentgens; each field the tumor dose being estimated at 775 roentgens. There was no evidence of radiation necrosis in the entire series. Marked skin reaction was noted but this cleared quickly at the conclusion of the series of treatments. Edema of the laryngeal mucosa sometimes persisted for from several months to years, but no permanent damage was observed.

The authors were impressed with the fact that they obtained excellent results by treating lesions found early in the stage of the disease. A better prognostic value is obtainable by use of this new classification as to stages of the disease.

MARCELO D. SACCH, M.D.

The Use of High Voltage Roentgen Therapy in the Treatment of Amenorrhea and Sterility in Women. I. L. KAPLAN. *Am J Roent* 94:5, 59-570.

Amenorrhea may be due to numerous and varied conditions. In some cases it is due to congenital or pathological malformations. For these irradiation is of no avail. Irradiation is useful in those cases in which the amenorrhea is a result of physiological dysfunction.

The reason for the efficacy of irradiation in the treatment of amenorrhea and sterility is still not definitely known. Several hypotheses are mentioned,

and case histories fitting each of these are presented (2) the selective action of roentgen rays upon ovaries (3) stimulation of an undeveloped uterus, (3) mechanical alteration of tissues due to swelling and hyperemia (4) roentgen destruction of mature and ruptured follicles.

Pituitary irradiation was also used. The reason for its beneficial effect is unknown.

The present study comprises a review of 338 cases. Only 334 of the patients were fully treated. Of these 33 were unmarried and 301 were married. Of the 274 cases followed favorable results were achieved in 12 unmarried and in 198 married women in 9 unmarried women and in 55 married women the treatment failed. Following irradiation 90 patients had normal full term pregnancies.

All patients were referred by gynecologists after all medical and hormonal therapy had failed. The period of sterility varied from several months to several years.

The factors used were 200 kilovolts, 4 to 5 milliamperes with 0.5 mm. of copper plus 1 mm. of aluminum filter with a skin target distance of 30 to 40 cm in early cases but 50 cm in all patients treated in the past 10 years. On the first day 50 roentgens of radiation were administered to the superior left and right ovarian fields and 75 roentgens to the anterior pituitary region. One week later, 75 roentgens were given to the posterior left and right ovarian fields. The third week, 50 roentgens were given to the anterior left and right ovarian fields and 75 roentgens to the anterior pituitary region. The dose into the ovaries must be between 10 and 14 per cent of the given dose measured in air.

The author believes that the irradiation outlined—properly administered—will harm neither the mother nor the offspring. JOSEPH P. TOMSILA, M.D.

External Irradiation with Roentgen Rays and Radium in the Treatment of Human Leucemias, Lymphomas, and Allied Disorders of the Hemopoietic System. ANNA HAMANN. *Radiology* 1948 50: 378.

The author reviews 337 cases which represent the number of patients who were treated by irradiation from 1929 to 1945. The series consists of patients with leukemia, Hodgkin's disease, lymphosarcoma, and polycythemia rubra vera. In all cases of Hodgkin's disease and lymphosarcoma the diagnosis is verified by biopsy. In 33 per cent of leucemias, confirmation was obtained by bone marrow aspiration or biopsy, lymph node biopsy, or at autopsy. The routine treatment in all four groups of disease was roentgen therapy given as local irradiation. Supplementary therapy was used which consisted of total body or wide field spray irradiation, radium therapy, and chemical agents. The chemicals were Fowler's solution in myelogenous leukemia, radioactive phosphorus in polycythemia rubra, and nitrogen mustards in selected cases of all groups.

The roentgen ray quality used was high value layer 1.5 mm. copper (200 kv., 1.0 mm. Cu. plus 1.0

mm. aluminum filter). On skin lesions and small superficial nodes the high value layer 0.24 mm. Cu (135 kv., 3.0 mm. aluminum equivalent intrinsic filtration only) was used.

In all patients with generalized disease the minimum doses necessary to produce a remission were given. Treatment courses were repeated only in the presence of symptoms and signs indicating activity of the disease—not prophylactically. In localized single manifestations of Hodgkin's disease and lymphosarcoma, high total doses of 2,000 to 4,000 roentgens were given. Total body or wide field spray irradiation was given chiefly to patients in advanced stages of the disease. The radiation quality in these treatments was high value layer 1.5 mm. copper. The maximum dose applied in advanced stages of Hodgkin's disease and lymphosarcoma was 200 roentgens D₀ to the anterior and to the posterior surfaces of the total body. Nitrogen mustard and radiophosphorus were used as adjunct treatments.

Six of the 49 patients with chronic myelogenous leukemia and 8 of the 51 patients with chronic lymphatic leukemia lived over 5 years. Seven of 143 patients with Hodgkin's disease lived over 10 years and 26 lived over 5 years. Three patients with lymphosarcoma lived more than 5 years. 2 without evidence of disease. In polycythemia rubra vera the results of roentgen therapy were not gratifying. The dosage required for effective roentgen therapy in this condition is high and does not allow frequent repeat courses. The roentgen therapy of leukemia, Hodgkin's disease, and lymphosarcoma judiciously given with the present methods is an effective palliative measure with a great margin of safety and few complications. The efficacy of total body irradiation is less clear. Supportive treatment with arsenicals is of real value in myelogenous leukemia. FRANK L. HUSSARY, M.D.

An Experimental Clinical Series in the X-Ray Treatment of Epitheliomas. J. VAN ROOZEN. *Clin. Proc. Cape Town*, 1947 6 Supp.

The author reports on the results he has obtained with x-ray therapy in 30 cases of epithelioma of various parts of the body (including the cheek, lip, nose, tongue, floor of the mouth, cervix, larynx, pharynx, and base of the tongue) by employing a 12 hour interval instead of the usual 24 hour or longer interval between treatments.

This experiment in this series of cases was based on the results of the experimental work of Reznor, Quimby, and McCoomb. Reznor showed that smaller doses given closer together caused less reaction of the normal skin than larger doses spaced further apart when the total dose and the time to administer the total dose were the same. Quimby and McCoomb showed that a greater measure of recovery from the effects of irradiation occurred during the first 6 to 12 hours after exposure than during the next 12 hours.

The beneficial effects from irradiation of a tumor depend on the sterilizing effects upon the tumor cells

and the recovery of the surrounding stroma to normality. Recurrence is more likely if the surrounding stroma has been irreparably damaged or destroyed. Irradiation of an epithelioma causes a speeding up of the process of keratinization and fragmentation of cells leading to gradual shriveling of the tumor and stops the delays mitosis which restores the normal balance between maturation and the new formation of cells.

The author found that by using a field of 150 sq cm. and radiation with a high value layer of 1.35 mm. of copper it required between 2,400 and 2,600 roentgens, given in eleven equal exposures at 12 hour intervals to produce the same erythema as is produced by from 1,800 to 2,000 roentgens given in six equal exposures at 24 hour intervals. Also he found that a total dose of from 2,600 to 3,400 roentgens could be given in eleven equal treatments every 12 hours with little or no resulting erythema. After the first few cases in his series, he found that a total dose of 2,400 roentgens given in eleven equal treatments every 12 hours was the optimum dose and would cause complete regression of the local epithelioma. Tumor growth in most of the cases without a marked skin erythema or damage to the surrounding stroma. He did not state whether the dosage represents roentgens in air or on the skin. In the treatment of carcinoma of the cervix it was noted to be tumor tissue roentgens and these were given through anterior and posterior pelvic and perineal

portals. This same x ray dosage produced similar results to those of 4,000 and 5,000 gamma roentgens of radium. The author regards a gamma ray dose of 4,000 roentgens over 5 days as adequate in the treatment of epitheliomas and a dose of more than 5,000 gamma roentgens as undesirable, because of the damage to the stroma.

With the stated x ray dosage for carcinoma of the cervix no radiation sickness occurred. The total body ionization was calculated to be between 10 and 12 mega gram-roentgens. Erythema will appear with smaller doses if the tissues have been irradiated previously.

Many excellent and impressive photographs are shown of patients who had been treated by this means. Because of the short time of his observation of these cases, the author does not claim to have cured any of the patients but he believes that the good results will prove to be permanent in half of the cases.

The advantages of this method of treatment are:

1. The course of treatments is finished in one week.

Epitheliomas of the skin and mucous membranes can be made to disappear with quantities of irradiation less than those required to produce an erythema of the skin or destruction of normal structures.

3. Radiation sickness rarely if ever occurs.

Vern W. Ritter, M.D.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Late Reactions to Metallic Foreign Bodies. THOMAS W. BOTTORF and D. RICHARD FREEMAN. *N. England J. M.* 1948, 338 385

The authors present their observations on a group of 40 male veterans with metallic foreign bodies who have undergone treatment at the Veterans Administration Hospital in West Roxbury, Massachusetts. It is known that when unabsorbable foreign bodies are imbedded in soft tissues they become surrounded by a fibrous capsule. In the presence of pathogenic and uninhibited bacteria, an abscess and a chronically discharging sinus tract may be formed; this reaction may be immediate or delayed, and its severity will depend on the virulence of the offending micro-organism. Foreign bodies may remain encysted for many years without causing symptoms. Bizarre migrations of foreign bodies, especially of sharp pointed objects occur.

The patients were grouped in the following 3 classes: those with (1) multiple regional foreign bodies with cellulitis, (2) single or multiple foreign bodies with abscess formation, (3) a single foreign body without infection but with pain. Penicillin was administered to patients with signs of infection beginning the day before operation, given penicillin beginning the day before operation which was continued until the wound was healed. A booster dose of tetanus toxoid was administered in all cases. The foreign body was removed along with the entire fibrous capsule and the excised specimens were examined histologically. Anaerobic and aerobic cultures of the foreign body were made in the operating room.

The basic principles of surgery for the removal of foreign bodies are accurate localization and control of infection. The authors controlled infected wounds as well as the actually septic wounds with the aid of antibiotics, sulfonamides and tetanus immunization. They successfully utilized the Berman foreign body locator as it accurately localized the foreign bodies and facilitated surgical procedures. With the aid of this locator the time required for the search for foreign bodies was also greatly shortened, and considerable trauma was avoided.

ROBERT TUKELL, M.D.

The Dynamics of Protein Metabolism. I. The Interrelationship between Protein and Caloric Intake and Their Influence upon the Utilization of Incorporated Protein for Tissue Synthesis by the Adult Protein Depleted Rat. EARL P. BENNETT, ELKANOR M. HUNFORD, ROBERT W. WISLER, HAROLD STEFFER, and OTHERS. *J. Lab. Clin. M.* 1948 33 357

To determine the relationship between the caloric intake and the utilization of proteins in the body

studies were carried out on rats which had for 2 months been carried on a diet which was adequate in all essentials except protein. At the end of the depletion period they were isolated into groups and fed definite diets. After 14 days of such diets the animals were sacrificed and the carcasses were divided into the various organs and other parts of the body which were then analyzed for their content of fat, water, protein and water soluble contents.

From these experiments the following observations were made: restriction of the caloric intake below a certain level restricts the utilization of ingested protein for the fabrication of tissue. The increase of the caloric intake above the critical level, however, does not augment the rate of utilization of a given quantity of protein above the maximum. Furthermore, the critical level appears to be 1240 calories per square meter per day and constitutes the energy necessary to cover the needs of maintenance storage, tissue synthesis and waste. Increasing the caloric level above the critical level results in an increase in the body weight largely by deposition of fat. With the caloric intake adequate, the utilization of protein is a function of the level of intake, utilization rising with increasing intake.

WILLIAM C. BECK, M.D.

The Dynamics of Protein Metabolism. II. The Relationship between the Level of Protein Intake and the Rate of Protein Utilization by Protein Depleted Men and Rats. EARL P. BENNETT, ROBERT L. WOOLDRIDGE, and ROBERT STEPTO. *J. Lab. Clin. M.* 1948 33 369

The authors assumed that the basic mechanisms for protein synthesis were the same for all mammalian species and tried to utilize a common denominator for comparison between man and animal in the utilization of protein. The basal metabolic unit, the caloric per square meter of surface per time unit, seemed to be such a factor. Comparable experiments demonstrated that both in man and rat both depleted of protein there was a striking resemblance in performance. In both the protein utilization paralleled the protein intake given an adequate caloric intake.

The basic energy requirements of animals varying in size from the mouse to the elephant have been found to be proportional to a function of the body mass which approximates mathematically the surface area. In a broad viewpoint therefore there is a general quantitative as well as qualitative pattern into which rats as well as man fit.

From these studies, the authors feel that the caloric intake in problems of nutrition has been overdrawn that while heat may be a necessary product of tissue activity it is after all a by-product that while a basic caloric requirement (which they estimate at 3600 calories per day) for the afebrile man at bed

rest is necessary a protein of high biologic value must be fed this must also be fed in excess of the quantity needed for nitrogenous equilibrium and, in general the higher the level of protein intake, the greater the rate of synthesis, if other elements of essential dietary are adequate.

It is believed that in figuring the caloric intake the proteins should not be included. In comparing the rat and the man, it is impossible to feed the man as much protein as the rat because of the relatively large surface mass ratio in the latter. Nevertheless, the data indicate that man can utilize up to 4 gm. of protein per kilogram per day. In order to obtain good rates of tissue synthesis, diets should contain between 2 to 4 gm. of protein per kilogram per day. Such intakes would assure a greater absolute rate of protein storage and a higher gross efficiency of protein utilization.

Procaine Penicillin G in Oil. Plasma Concentrations: Preliminary Observations on Its Use in Pneumonia. WILLIAM P. BOGER, JACQ E. ORITT, HAROLD L. ISRAEL, and HARRISON F. FLEPPEN. *Am J Med Sc* 948, 5, 50.

Procaine penicillin G is a combination of equimolar quantities of penicillin G and procaine base to form a crystalline salt which is relatively insoluble in water (less than 0.7 per cent at 5°C.) Because of its low solubility a slowed release of penicillin into the circulation occurs after intramuscular injection of the substance a phenomenon that is in effect (but not cause) similar to that of the penicillin in oil and beeswax formula of Romansky in which the prolonged penicillin effect (delayed absorption) is achieved by the oil and beeswax milieu. Allergic reactions, sterile abscesses, and severe pain at the site of injection have occurred sufficiently frequently with the oil and wax preparation so as to prejudice many physicians against its use hence the search for a substitute such as procaine penicillin which is wax-free.

Utilizing procaine penicillin G in a sesame oil suspension containing from 300,000 to 600,000 units of penicillin per injection, the authors observed no local pain or systemic toxicity in 50 patients. Plasma concentrations of penicillin above 0.039 units per cubic centimeter after a single injection of 300,000 units of procaine penicillin varied from 6 to 30 hours in a group of ambulatory control patients, and from 7 to 70 hours in a group of 10 pneumonia patients with an average for the two groups of 13 and 33 hours respectively. Eighteen of 23 patients suffering from bacterial pneumonia recovered without complication following a single intramuscular dose of from 300,000 to 600,000 units of procaine penicillin G in oil. Two patients relapsed under this treatment and 3 failed to respond. The authors conclude that a single injection of 300,000 units of procaine penicillin G in oil will, in the average patient, give a satisfactory plasma concentration of penicillin, or a suppressive antibacterial action for at least 4 hours.

The Origin of Edema in Anemia (Ueber die Entstehung anaemischer Oedeme). MICHAEL FÖLDES, AX DREAS KORÁNYI, and GEORGE SZABO. *Int med scand* 948, 59, 486.

An investigation of the role of capillary permeability in the development of edema in patients with anemia was carried out. The method of Landis was used this consists of constricting the upper arm for 30 minutes with a pressure of 40 mm. of mercury and at the end of this period determining the hematocrit value and the albumin concentration of the venous blood. Venous blood from the unconstricted arm being examined for comparison. From these values one can calculate the fluid mass (per 100 c.c. of blood) that leaves the vessels. The albumin concentration of the extravasated fluid and the colloid osmotic pressure were also determined.

In the majority of patients with anemia a significantly increased capillary permeability was detected, and the filtered fluid contained more or less albumin. Under normal circumstances the fluid which filters through the vascular walls is albumin free. There was no correlation between the colloid pressure and the filtration but there was a correlation between the hemoglobin concentration and the filtration.

From these experiments it appears that the chief cause of water retention in anemia is increased permeability of the capillary endothelium. There is a close relationship between the increased permeability and the degree of diminution of hemoglobin concentration.

Experimental Investigations on the Anesthetic Infiltration of the Sino-glandocarotid Zone as a Treatment of Traumatic Shock (Indagini sperimentali sulla infiltrazione anestetica della zona seno-glandocarotidea quale terapia dello shock). VINCENZO DEL BELLO. *Ann Ital chir* 947, 24, 550.

The carotid sinus, a dilatation of the internal carotid artery constituting together with the carotid gland the so-called sino-glandocarotid zone. This zone is very sensitive to variations in pressure regulating the cardiac frequency and arterial pressure and also influences the respiratory rhythm. It also has the action of reestablishing equilibrium on the endocranial circulation. According to the latest research, the nervous endings in the carotid sinus perceive the pressure variations, whereas the chemical excitants affect the carotid gland.

The beneficial results following the anesthetic infiltration of the carotid sinus as a treatment for shock have recently been reported. These have been reported following clinical applications. The author decided to conduct animal experiments in order to explain these results. In man the zone is infiltrated by inserting the needle along the anterior margin of the sternocleidomastoid muscle at the level of the superior margin of the thyroid cartilage with the neck in hyperextension. In the dog, however the zone is more difficult to find and the author resorted to exposing it and ligating it so that he could bring

it externally when he wanted to inject it and in this way be positive of the area he was injecting.

The beneficial effects produced are explained according to the idea of Leger who believes that the anesthetic infiltration of the carotid sinus acts in shock by causing a discharge of corticoadrenal hormone and that this improves the capillary atony and arterial hypotension. The author would like to add that among the various causes for shock the vagosympathetic imbalance plays some part also that the pericarotid infiltration will cause an improvement of the cerebral circulation. The infiltration is believed to correct the nervous imbalance.

The author reviews the literature on shock and makes numerous references to the works of Blacklock, Phenister, Cannon, Moon, Allen, Rosenthal, Harlins and other American authors.

Observations of Burn Scars Sustained by Atomic Bomb Survivors. A Preliminary Study. Mizushima A., Block and Masao Tsuruki. *Am J Surg* 1948, 75: 477

Many of the burns sustained by atomic bomb survivors have healed with accumulations of excessive amounts of elevated scar tissue, many having the gross appearance of severe scar keloids. An observational study was made on survivors at Hiroshima and Nagasaki as well as on patients in Tokyo hospitals who had been burned from other causes than the atomic bomb explosion.

The burns seen in 1945 after the atomic bomb explosions were largely flash burns, the result of radiant heat emitted at the time of the explosions and thus they were limited to exposed areas of the skin or to places where overlying clothing was in intimate contact with the skin. All degrees of severity of burns were seen. The majority of the survivors had within 4 weeks. However, nearly all burns of second degree or worse became infected and their healing was usually delayed. Treatment of the burns was limited largely to local applications and dressings; relatively few patients received transfusions and early skin grafting was not done.

The keloids and hypertrophic scars continued, in general to increase for a few months after their presence was first noticed. Their surfaces were smooth and shiny but wrinkling of the surfaces appeared after about a year which indicated contraction. Some scars decreased slightly since the spring of 1946 but large numbers of contractures occurred at locations where these usually develop. The areas of scar keloid as now seen typically occupy the central part of the burned area where the burn was most severe and where it healed last. Areas involved vary from a few centimeters in diameter to almost complete coverage of the back or forearm.

A major problem in the study was the determination of the exact nature of a scar keloid. It was not possible from clinical observations and histologic studies of excised scar tissue to arrive at a definition

that would separate keloids from hypertrophic scars. It would seem that keloids and hypertrophic scars differ only in the degree of accumulation of scar tissue after healing of the surface of the lesion.

In this study, 90 patients who were survivors of the atomic bomb explosions were studied along with 25 Japanese patients who received burns from causes other than the atomic bomb. Of the 90 bomb survivors 49, or 54 per cent, developed scar keloids of varying degrees. Of the 25 patients burned from other causes, 13 developed scar keloids.

It was believed that plastic surgery had been done on too few of the patients to warrant conclusions regarding the frequency of recurrence of keloids and occurrence of keloids in donor sites for skin grafts. Three of 10 patients who had received grafts following removal of keloids showed recurrence of keloids and 3 others developed hypertrophic scars in the grafted areas. These recurrences were usually located where the grafts had apparently not taken well. Four of 8 patients developed keloids along the lines of closure following excision of the keloids with primary closure.

In regard to the incidence of keloid formation among the Japanese the best available evidence indicates that perhaps they have a slightly greater tendency toward keloid formation than the white race but not so great a tendency as the Negro race. In general the data indicate that the keloids produced represent no peculiar effect of the atomic bomb explosion since similar keloids were found in other Japanese sustaining ordinary thermal burns. In addition it seems probable that a similar incidence of keloids could have occurred in burns of the same severity from any other cause under similar conditions during the healing of the lesions in patients having the same general state of health.

FRANK F. KANTHAKE, M.D.

Plasma Cell Tumors. G. LUMB and T. M. PROSSER. *J Bone Surg* 1948, 30B: 125

The authors review the historical data and the opinions of other authors on multiple myeloma and present their own impressions based upon a careful review of 15 personal cases. Three main types of tumors are recognized: bone marrow tumors, extramedullary tumors and those which have spread generally from one of these two sources either to the viscera or as a plasma cell leukemia. Although it is admitted that the bone tumors may be single, the authors state that one must be sure that a single tumor is not the first expression of what may later become a multicentric disease. For this assurance most common and usually the first symptom. Pain is the general symptoms appear but only when the tumors are multiple. These consist in malaise, weakness, anemia and cachexia. The complications are pathological fracture and compression paraplegia in the spinal forms.

The extramedullary tumors are often mistaken for carcinoma and usually are present in the mouth and

upper air passages. More rarely they are observed in the conjunctiva lymph nodes pleura mediastinum spermatic cord, thyroid gland ovary intestines kidneys and skin. They may have a variable history following all variations from a completely benign course to local and even distant invasion, while others have an ultimate bone involvement indistinguishable from multiple myelomatosis.

In discussing the morbid anatomy and microscopic appearance of these tumors, the authors call attention to the fact that the degree of malignancy can be estimated by the degree of variation in the cell type the frequency of mitotic figures and evidences of local invasiveness. These features were most marked in their cases which showed multiplicity than in those with solitary lesions. In the nasopharyngeal tumors, the differentiation between these and granulomatous lesions may be difficult. The uniformity of the cellular pattern, the absence of organisms, and failure to invade the surface epithelium, as well as their radiosensitivity suggest their neoplastic nature.

The biochemical features are discussed. These include the presence of Bence-Jones protein and the abnormal serum protein as well as the frequently concomitant amyloidosis. There may be renal changes, plasma cell invasion of the liver and spleen, and finally anemia and a plasma cell leucemia.

The authors believe that the various clinical and pathologic types merge into one entity further that the widespread disease is not one of metastasis, but rather of changes of multifocal origins and that the disease may exist in a variety of forms which should not however, be considered as different manifestations of the disease, but rather as gradations in extent and activity of the same disease process.

DUCTLESS GLANDS

The Role of the Steroid Hormones in the Relaxation of the Symphysis Pubis of the Guinea Pig. M. A. ZARROW *Endocrinology* 1948, 41: 19.

Relaxation of the symphysis pubis of the guinea pig may be produced by treatment with (a) estradiol (b) estradiol and progesterone, and (c) estradiol and relaxin. In the castrated, hysterectomized guinea pig progesterone is without effect where as in the presence of a uterus, treatment with both estradiol and progesterone shortens the time required for pelvic separation as compared with estradiol treatment alone, and results in the formation of endogenous relaxin.

Relaxin is effective in both castrated and castrated and hysterectomized guinea pigs which have been pretreated with estradiol and produces relaxation in 6 hours. This is a much shorter time than that following treatment with estradiol alone or estradiol and progesterone.

It is concluded that relaxation of the symphysis pubis of the guinea pig may take place by means of two different procedures (1) prolonged treatment with estradiol, which apparently has a direct effect on the symphysis, and (2) treatment with relaxin—exogenous relaxin may be injected into an estrogen-primed guinea pig or endogenous relaxin may be formed after treatment with estradiol and progesterone in the presence of a uterus.

It is noted that optimum relaxation with the steroids is obtained when progesterone and estradiol are given simultaneously. Desoxycorticosterone acetate is approximately one-tenth as active as progesterone in its ability to produce the formation of relaxin and pubic relaxation.

CARCINOMA OF THE STOMACH

The Validity of Basing Prognosis upon Borrmann Typing or the Presence of Metastases

GEORGE E. MOORE, M.D. DAVID STATE, M.D., F.A.C.S.

ROBERT HEBBEL, M.D., and ALAN E. TRELOAR, Ph.D. Minneapolis, Minnesota

IN this paper is presented an analysis according to Borrmann's classification, of the relative influences of regional metastases and the gross anatomic types of gastric carcinomas on postoperative survival.

Schindler has recently offered evidence that the prognosis and perhaps the advisability of any therapeutic procedure for carcinoma of the stomach may be based upon the Borrmann type of the tumor. Borrmann separated the gastric carcinomas into 4 gross types: I, sharply demarcated polypoid carcinomas; II, sharply demarcated ulcerated carcinomas; III, partly infiltrating carcinomas; IV, diffusely infiltrating carcinomas. Combining types I and II as limited and types III and IV as infiltrative groups, Schindler noted that there was a much higher resectability rate and lower mortality rate for the former group. Of a series of 239 cases which he analyzed, resection was performed in 167. Exclusion of postoperative deaths and palliative resections left 107 resections for cure. Of this group among those in which both the course and type of tumor were known there were 7

three year cures (3 type I, 3 type II and 1 type IV) and 4 five year cures (2 type I, 2 type II). It was concluded that the patient with a limited tumor has a 10 to 13 times greater chance of a three year cure than has the patient with an infiltrative tumor, and that for the latter no 5 year cure appears possible. On the basis of his data, Schindler questioned the advisability of resection of infiltrative tumors.

This view challenges the belief that as many carcinomas as possible should be resected and served as the stimulus for a review of the material at this clinic with special reference to Borrmann types of tumor. Another point however seemed to be of probable importance. It is obvious that survival is dependent on complete removal of the tumor and the likelihood of such removal should in the case of the stomach just as for other organs such as the breast, be to a degree reflected in the presence or absence of regional metastases. We have consequently compared the effects of the gross anatomic types of carcinoma and regional metastases upon the survival rates.

PRESENTATION OF DATA

In the period 1938-1943 inclusive the diagnosis of carcinoma was made in 342 individuals and gastric resection was performed on 177 of the group. The follow up is complete

to June 1947 in all cases. The data presented however concern only the 124 patients whose resected stomachs were available for re-examination and suitable for accurate determination of the Borrmann types of the tumors.

Although most tumors fall readily into the Borrmann types here as in other classifications, one must be arbitrary in some instances. We have been particularly critical of the determination of the limited tumors (types I and II). The extent of a tumor as determined by inspection of its surfaces and palpation is sometimes deceptive and we have also examined cut surfaces in order more accurately to segregate those tumors which presented a clearly defined advancing border. The several group designations concern only the manner of growth and have nothing to do with size. Thus, type IV tumors may range from small lesions apparently confined but without demonstrable borders, in a small segment of the excised stomach to those which obviously infiltrate the entire organ. Those specimens which included direct extensions to adjacent organs such as liver or colon have been classified with respect to the character of the tumor and such direct extensions have not been classed as metastases.

The presence of metastases in lymph nodes was determined by routine methods of examination. In instances in which the original examination had failed to demonstrate involved nodes the specimens were searched for further nodes, which if found, were sectioned. For the purposes of this paper no distinctions are made

relative to numbers of nodes involved and they are considered simply as positive or negative for metastatic carcinoma.

For the 124 patients the distribution of the Borrmann types was as follows: 4 (3.2%) were of type I, 35 (28.2%) were of type II, 27 (21.7%) were of type III, and 58 (46.8%) were of type IV. Combining types I with II and III with IV the series presents 39 (31.4%) 'limited' tumors and 85 (68.6%) 'infiltrating' tumors. This distribution approximates that found by Schindler in 87 cases where 34.5 per cent were limited and 65.5 per cent were infiltrating.

Table I summarizes the course followed by the 124 patients with reference to the Borrmann types of their tumors. There were 24 postoperative deaths. For the limited tumors (types I and II) the mortality rate (6 of 39 patients) was 15.4 per cent. For the infiltrating tumors (types III and IV) the mortality rate (18 of 85 patients) was 21.2 per cent. One hundred patients survived resection and were discharged from the hospital. Their further course is shown in Table I and is summarized relative to both type of tumor and metastases in Table II. All of the deaths in this group have been due to recurrence of carcinoma. A few patients have lived 3 years but have not yet lived 5 years. They are included among those listed as living in June, 1947 in Tables I and II.

Of the 4 patients with type I tumors, 3 (3 without and 1 with metastases) survived 3

years One patient (without metastases) survived 5 years

Twenty-nine of 35 patients with type II tumors survived resection and of this group 20 (17 with demonstrable metastases) failed to live 3 years. Nine patients (5 without and 4 with metastases) survived 3 years. Five patients (4 without and 1 with metastases) survived 5 years. An additional patient (with metastases) was living and well in June 1947 but had not yet survived 5 years.

Twenty-one of 27 patients with type III tumors survived resection and of this group 12 (all with metastases) failed to live 3 years. Nine patients (4 without and 5 with metastases) lived 3 years. Four patients (1 without and 3 with metastases) have survived 5 years. An additional 2 patients (one with and one without metastases) were living and well in June 1947 but had not yet survived 5 years.

Forty-six of 58 patients with type IV tumors survived resection and of these 38 (3 without metastases) failed to live 3 years. Eight patients (4 with 4 without metastases) lived 3 years. Three (without metastases) lived 5 years. An additional patient (without metastases) was living and well in June 1947 but had not yet survived 5 years.

From the data in Table I it may be seen that, combining types I and II as limited tumors

and types III and IV as infiltrating tumors among those patients who survived resection there are 33 limited and 67 infiltrating tumors. The 33 patients with limited tumors account for 12 of the 29 three year survivors and 32 of them accounted for 6 of the 13 five year survivors. The 67 patients with infiltrating tumors provided 17 of the 29 three year survivors and 64 of them provided 7 of the 13 five year survivors. Thus it is apparent that although the patients with limited tumors make up the smaller group they provide a proportionately larger share of the 3 and 5 year survivors. It may be seen in Table II that 21 patients representing all Borrmann types in whom metastases were not demonstrated provided 15 three year survivors, and 20 patients without metastases provided 9 five year survivors. Of 79 patients with metastases 14 survived 3 years and of 76 with metastases 4 survived 5 years. The question is then raised whether it is the gross type of carcinoma which is crucial to survival or whether an other variable related to the type of tumor, namely metastases is more important. It is pertinent to know what each contributes to the total correlation with postoperative survival independent of the other variable.

The data have been subjected to statistical analysis. The material is not large enough to

permut segregation into each of the four Borrmann types without raising serious statistical problems relative to small numbers. Therefore the types were grouped as indicated into limited and infiltrating tumors. The 100 patients who survived resection were divided accordingly and within each group the determination of the relationship of metastases to 3 year survival is freed of the influence of the Borrmann type since the latter variable is held constant. Likewise the relationship between Borrmann type and survival was determined by dividing the patients into 2 groups representing those with and those without metastases, thus holding the latter variable constant. The 5 year survival rates were similarly considered for the 96 patients concerned.

The relationship of metastases to survival, freed of the influence of the Borrmann types is shown in Tables III and IV for 3 and 5 year survivals, respectively. The first entry in each basic cell of the tables defines the actual frequency a . The next specifies the theoretical number t of cases to be expected in each cell if no relationship exists between metastases and survival. The remaining entry is the deviation of the actual frequency from the theoretical, alike in number in all 4 cells but differing in sign.

The data of Table III show that among 33 patients with limited tumors, 7 of 10 without metastases and 5 of 23 with metastases sur-

vived 3 years and that among 67 patients with infiltrating tumors, 8 of 11 without metastases and 9 of 56 with metastases survived 3 years. Table IV shows that among 32 patients with limited tumors, 5 of 10 without metastases and 1 of 22 with metastases survived 5 years, and that among 64 patients with infiltrating tumors, 4 of 10 without metastases and 3 of 54 with metastases survived 5 years.

The association between survival and metastases is definite within both groups of carcinomas. In each of the tabulations (panels A and B of Tables III and IV) more patients died when metastases were demonstrated and more lived when metastases were not found than should theoretically be expected if metastases did not affect the probability of 3 or 5 year survival. It is clear that these differences are not chance deviations because the χ^2 criterion shows each considered alone, to be significant¹. Taken collectively there is no reason to doubt that the association is real. The χ^2 values for the two panels of Table III may be combined, giving a P of considerably less than 1 in a thousand. Similarly the two panels may be combined in Table IV where it is found that P lies between 1 and 2 per thousand.

A probability of less than 5 per cent that each set of 4 differences would arise through chance alone is considered here as significant. This conforms to standard practice in statistical analysis.

The relationship of the Borrmann types to survival considered independent of the presence or absence of metastases is shown in Tables V and VI for 3 year and 5 year survivals respectively. Among 21 patients without metastases 7 of 10 with limited tumors and 8 of 11 with infiltrating tumors survived 3 years. Of 79 patients with metastases 5 of 23 with limited tumors and 9 of 56 with infiltrating tumors survived 3 years. Among 20 patients without metastases 5 of 10 with limited tumors and 4 of 10 with infiltrating tumors survived 5 years. Among 76 patients with metastases 1 of 22 with limited tumors and 3 of 54 with infiltrating tumors survived 5 years.

In each of the cells of Tables V and VI the actual frequency deviated from the theoretical (based on no association) by less than unity and in 3 of 4 tabulations (panels A and B of Table V and panel A of Table VI) the agreement with expectation is as close as it can be since observed frequencies must be whole numbers. The one tabulation (Table VI B) in which a statistical test for real discordance has some meaning yields a probability that such discrepancies or worse would arise by chance approximately 4 times out of 5 (P is 0.8, approximately). It is therefore demonstrated that when the presence or absence of metastases is ignored, the Borrmann classification owes its relationship to postoperative survival solely to the fact that the infiltrating forms have a higher probability of metastases.

COMMENT

Schindler suggested that in view of the poor prognosis in patients with infiltrating tumors the combined use of gastroscopy and x ray might serve to separate patients with limited tumors as the more likely candidates for surgery. His contention however, that clinical determination of the Borrmann type might form the primary basis of decision as to operative interference seems now to rest on the correlation between the gross types and the presence of metastases. Tables I and II show that the correlation is not perfect. Of 67 patients with infiltrating tumors 17 survived at least 3 years and 8 of the 17 showed no metastases. Of 33 patients with limited tumors, 21 failed to live 3 years and of these, 18 had

metastases. The Borrmann types alone then even when determined postoperatively, prove to be inadequate indicators of the wisdom of surgical procedures. On the other hand we find that there is the probability of survival for a period of 3 years in approximately 70 per cent (15 of 21 patients) of those cases in which metastases are not found but that the probability falls to about one-quarter of that figure when metastases are demonstrated (17 of 79 patients).

The examination employed for determination of metastases is relatively crude. Sample sections of nodes undoubtedly miss some small metastases; some small nodes are not found, and there is in addition no certainty, for any given specimen, that all tumor bearing nodes have been removed. However, the data indicate that for gastric carcinoma, as for carcinoma elsewhere in the body, the likelihood of complete removal of tumor bearing tissue is reflected to a high degree in the determination, even by routine methods, of the presence or absence of metastatic tumor in the regional lymph nodes.

To the extent that the infiltrating tumors are less readily excised without leaving microscopic extensions in the gastric wall and more likely to have metastasized, they offer a poor prognosis compared to the limited tumors. However in some patients infiltrating tumors are confined to excised tissue to a degree consistent with long survival. The limited tumors offer a better prognosis only when lymph nodes are not involved and the presence or absence of metastases cannot be determined preoperatively. To restrict surgical excision to those patients with limited tumors would deprive some patients though admittedly few with infiltrating tumors of the chance for long survival and many more of palliation with reasonable comfort for periods averaging up to 2 years (State, Moore, and Wangenstein). Without therapy most patients live but a few months after the diagnosis is established. In view of the low risk and short convalescence accompanying gastric resection, it would appear difficult to argue that the opportunity of over 22 months of relative comfort and the chance of longer survival should be withheld from any patient.

Thus it would seem that attempts to predict the survival of patients with carcinoma of the stomach by the gastroscopic typing of their lesions are not justified. If patients with Borrmann types III and IV are denied operation a certain number of lives will be needlessly lost. It has been shown that these patients do have a reasonable chance of survival if no metastases are present.

It may further be noted that the kind of data upon which this study is based has now been improved. In 1945 the operability rate for carcinoma of the stomach at this clinic was 89 per cent, resectability 79.6 per cent and the mortality rate 4.8 per cent. In addition the recent introduction of the thoracoabdominal approach has increased the chances of removing infiltrating and high lying lesions as well as metastases. In the last 16 total gastrectomies at this clinic, there has been but one death. These techniques should favorably influence the removal of infiltrating lesions, and contribute to longer survival.

CONCLUSIONS

1. The presence or absence of demonstrable metastases in regional nodes among patients subjected to gastric resection for carcinoma has a greater prognostic value than does the Borrmann type of the tumor.

2. The Borrmann type affects the prognosis of groups of cases to the extent that the limited tumors provide a proportionately large number of patients free of metastases while the infiltrating tumors which are more numerous are more likely to have metastasized.

3. The presence or absence of metastases cannot be accurately determined preoperatively and no patient should be denied operation because of the type of tumor he may be determined to have.

THE FIVE YEAR SURVIVAL RATE IN CASES OF COMPLETELY OBSTRUCTING ANNULAR CARCINOMA OF THE DESCENDING COLON AND SIGMOID

A Pathologic Study

DAVID F. NICKELL, M.D., and MALCOLM B. DOCKERTY, M.D., Rochester, Minnesota

OBSTRUCTION superimposed on an existing malignant lesion of the colon is a serious complication. Long before 1810 when Thomas Copeland described stenosing carcinoma of the colon many procedures, beginning with the decompression colostomy first performed by Littre in 1710 had been devised for relief of this condition. By 1839 Amussat, the French surgeon, was performing decompression colostomy on both the right and left halves of the colon. Later attempts were made to extirpate the malignant lesion. Kohler in 1881 reported the first successful resection. Mikulicz in 1903 described his exteriorization procedure and reported a mortality rate of 12.5 per cent in 76 cases. Miles at the turn of the century, favored the combined abdominoperineal approach. In every procedure, however, obstruction continued to plague the surgeon, keeping his operative mortality uncomfortably high. With the advent of chemotherapy there is little doubt that the mortality rate has been revised downward. But what of the 5 year survival in cases in which obstruction complicates the presence of colonic carcinoma?

We have felt for some time that obstruction itself in some way decreases the expected 5 year survival rate. A review of the literature offered little actual statistical support of this hypothesis. However, 5 important points were brought out which were conceded to be contributing factors. (1) Damage to the bowel wall by the increased intraenteric pressure has been reviewed and studied by many men (2, 14-18) who have shown that permeability of the wall of the obstructed colon is increased and that lymphatic absorption appears to be

increased. We believe that this may also facilitate earlier metastasis of carcinoma cells. (2) The inflammatory swelling, distention, engorgement of vessels and edema of the intestinal wall and of the carcinoma itself probably tend to break down any protective forces. (3, 8, 10, 11) brought into operation by the tissues of the host. (3) The increasing hypertrophy of the musculature of the colon and the attempts by the bowel to force fecal material through an increasingly smaller aperture may result in traumatizing and vigorous massaging of the tumor (7, 8) which may induce earlier and more widespread metastasis. (4) The motility of cancer cells is of debatable significance but such motility was demonstrated by Cornalt in 1872 and again later (8, 9). Also there exists the possibility of the elaboration by carcinoma cells of some lytic or other damaging property which enables malignant cells to break through the basement membrane and invade the deeper tissues. Whatever this invasive property might be, the intestinal wall damaged by obstruction would offer an easier pathway of extension. (5) The ileocecal valve when competent produces a closed loop type of obstruction. Whether it is done by valve or sphincter action, the relatively low intraenteric pressure produced, if it is exerted for 27 to 32 hours, will destroy the viability of the bowel or definitely impair its normal function. (18) The aforementioned changes in the wall are accentuated.

FACTORS CONTRIBUTING TO THE OBSTRUCTION

Gruenfeld listed 4 factors contributing to the development of colonic obstruction, namely (1) inflammatory edema, (2) impaction of solid feces, (3) kinking of the bowel with varying degrees of intussusception, and

From the Division of Surgery, Mayo Foundation and the Section on Surgical Pathology, Mayo Clinic.

(4) fatigue of the intestinal muscle above the point of stenosis. Rankin considered 3 factors in reference to the left versus the right portions namely (1) the character of the intestinal wall itself which is less elastic and smaller in diameter than its fellow in the right half (2) the fecal current which is formed and hard in contradistinction to the liquid stream of the right side and (3) the pathologic characteristics of the growth which in lesions of the left portion of the colon has a tendency to encircle the lumen and thus bring about slow stenosis. From our study of the size of the obstructing annular lesions as compared to similar nonobstructing lesions we would conclude as others have that the obstruction is dependent too on the amount of fibrosis present a reaction on the part of the host to the presence of cancer cells.

PURPOSE OF STUDY MATERIAL AND METHODS

Purpose We have often noted in the operating room and in the surgical pathology laboratory that at the time of the initial exploration involvement of the regional nodes or metastasis to the liver frequently is associated with small but obstructing carcinomas of the left part of the colon. We have observed, too that patients who have undergone resections for favorable lesions of small size often returned in from 1 to 3 years because of unmistakable signs or symptoms of metastatic carcinoma. We therefore considered examination of the factor of obstruction as pertinent in the 5 year survival rate of patients who had obstructing annular carcinoma of the left portion of the colon.

Material Two hundred and fifty four cases of carcinoma of the left portion of the colon in which operation had been performed in the 36 years, 1910 through 1945 and in which obstruction was present, were reviewed. All cases were discarded except those in which complete clinical obstruction was present and for which cecostomy or colostomy was required for decompression. All lesions of polypoid type were discarded. All cases of carcinoma occurring at or below the peritoneal fluid and at the splenic flexure were eliminated in order that we might determine the reaction of the bowel to the obstruction both as to the per-

centage increase in the circumference of the lumen above the carcinoma and to the percentage increase in the thickness of the muscularis propria above the lesion. The final group studied consisted of 78 cases of completely obstructing annular carcinoma of the sigmoid and descending colon. In 55 of these the lesions occurred in the sigmoid and in 23 in the descending colon. All lesions had been removed surgically and the specimens had been preserved in 10 per cent commercial formalin (40 per cent formaldehyde). For comparison all cases of surgically removed non-obstructing carcinomas of the descending colon and sigmoid encountered at the Mayo Clinic in 10 years, 1930 through 1939 were studied again all cases of polypoid type were excluded. This control group totaled 329 cases.

In order to determine the incidence reference is made to the total of 2,089 cases of carcinoma of the descending colon and sigmoid in which operation was performed at the clinic during the 36 years covered by the detailed study.

Methods Gross pathologic studies were carried out on each specimen to ascertain that it was in fact completely occluding the lumen of the bowel and that it was an annular or napkin ring type. Each carcinoma was carefully measured in three dimensions to determine the cubic content of tumor tissue. The circumference of the lumen and the thickness of the muscularis propria were measured proximal and distal to the carcinoma to the nearest 0.5 millimeter and charted. Blocks of tissue then were cut from the proximal and distal edges of the tumor and at the peritoneal surface for grading (Broders) and classification by Dukes method. A careful search was made for involved nodes and each was sectioned for study. All specimens were placed in fresh 10 per cent solution of formalin and later studied under the microscope in paraffin sections stained with hematoxylin and eosin.

INCIDENCE AGE, AND SEX

Annular carcinomas comprise 60 to 70 per cent of all carcinomas of the colon encountered clinically and require in an average case, about 2 years to encircle the bowel completely

TABLE I — OBSTRUCTING AND NONOBSTRUCTING CARCINOMA* OF THE DESCENDING COLON AND SIGMOID A COMPARISON OF THE GRADE OF MALIGNANCY

Grade	Nonobstructing		Obstructing	
	Cases	Per cent	Cases	Per cent

Total	180	100	78	100

*Polypoid lesions, large percentage of which are grade 3 are not included in this series.

(4) Nevertheless obstructive phenomena dominate the clinical picture of carcinoma of the left part of the colon with 75 to 80 per cent of patients having obstructive symptoms at the time they first consult a surgeon (1, 5, 12, 13). A higher percentage give roentgenologic evidence of obstruction and about half of these patients have colicky pain (1). Obstruction is usually a late sign of malignant growth of the colon which occurs as a slowly progressive process. About 5 per cent of patients however will have signs of acute obstruction as the first symptom (13, 14). In our series 2,089 patients with carcinoma of the sigmoid and descending colon have been operated on. In 154, an incidence of 12.2 per cent acute or subacute obstruction grade 1 to 4 (grade 4 represents complete obstruction) was found. Complete obstruction was present in 78 cases an incidence of 3.7 per cent for the entire group and 30.7 per cent for the group in which some degree of obstruction was encountered. Therefore in about a third of cases in which obstruction was present, complete obstruction had occurred before the surgeon saw the patient.

There were 41 women and 37 men in this series. The number of women in the younger age groups was somewhat greater than of men.

PATHOLOGIC DATA

Size. It is generally agreed that there is little correlation between the size of a malignant colonic lesion and the degree of obstruction present. In our series of 78 cases however paradoxically enough, the cubic contents of

TABLE II — FIVE YEAR SURVIVAL RATE ACCORDING TO DUKES CLASSIFICATION AND BRODERS GRADING

Dukes classification	Traced patients	Lived 5 or more years		Broders grade	Traced patients	Lived 5 or more years	
		Number	Per cent			Number	Per cent
A	11	4	36.4			1	5
B	9		1		5	7	8
C	15	3	20	3	7	1	14.3
				4	1	0	—
Total	35	0	5.7		35	9	17

the lesions which produced obstruction averaged 40 cubic centimeters as against 64 cubic centimeters for those which were not obstructive (control series).

Grade. Apparently the grade of the lesion and the incidence of obstruction are not related (Table I). Although our series of cases is small the incidence of the obstructing and nonobstructing lesions of various grades of malignancy is similar. The 5 year survival rates in cases graded by the Broders method and also classified by Dukes method are recorded in Table II. We do not intend to imply that Dukes classification is not of value for we know that it is in other and larger series. However the statistics in this series indicate that obstruction in some way materially alters the 5 year expectancy as 'predicted' by Dukes' method of classification.

Hypertrophy and dilatation. Seven specimens could not be accurately studied from the standpoint of hypertrophy and dilatation. Two were gangrenous, and 5 had been subjected to exteriorization and were so distorted that accurate measurement was impossible. In the remainder we found the mean thickness of the muscularis propria above the lesions to be exactly double that of the mean thickness below the lesions (2.66 and 1.33 mm. respectively) and the circumference of the lumen above the lesions to be approximately double that of the circumference below the lesions (7.93 and 4.50 cm., respectively). All of these specimens had been preserved in formaldehyde and it is probable that there was a greater percentage of shrinkage in the proximal edematous part of the bowel than of the more normal distal part and that the actual

Fig. 1. Comparison of increase in size of lumen to increase in size of muscularis above the obstructing carcinoma.

percentage increase in the luminal circumference was greater than that shown and that there was a similar but less striking difference in the muscularis propria.

In approximately 80 per cent of cases the percentage increase in the size of the muscularis propria above the tumor was greater than the percentage increase in the size of the lumen, whereas in approximately 20 per cent the percentage increase in the size of the lumen of the bowel was greater (Fig. 1). One might think that this 20 per cent represents cases in which obstruction was of short duration. However in 3 of the cases (about 20 per cent) in which the increased dilatation was greatest obstruction had been present for only 1 day before surgery in 5 for 7 to 14 days and in 4 between 2 and 5 days.

RELATION OF DAYS OF OBSTRUCTION TO THE SURVIVAL RATE

The relationship of the duration of obstruction in days before operation to the survival

rate was investigated. The duration of obstruction was taken from the records and in some cases only an approximation could be made. No relation between duration of obstruction and length of survival is evident. It was somewhat of a surprise to see that 4 of the 9 patients who lived 5 years after operation had had obstruction for 7 days to 2 weeks before operation. We expected to find a higher incidence of 5 year survivals in cases of obstruction of short duration, but our data do not substantiate this impression. One explanation may be that complete obstruction occurred early in these cases and that impairment of the mesenteric circulation and decreased intestinal activity eliminated the factor of massage or an incompetent ileocecal valve prevented a closed-loop type of obstruction with minimal damage of intestinal wall.

THE FIVE YEAR SURVIVAL RATE

Of the 78 patients who had completely obstructing annular carcinoma of the descending

*Hospital deaths not included in this series.

†All patients who had resections of the colon for nonobstructing adenocarcinoma at the clinic from 1930 to 1939 inclusive are included.

‡All patients who had resections of the colon for obstructing adenocarcinoma of the descending colon or sigmoid at the clinic from 1930 or earlier are included for the determination of the 3 year survival rates and those who had them in 1941 or earlier for the determinations of the 5 year survival rates.

colon and sigmoid 39 were seen in 1939 or earlier. Since the follow up for survival was as of January 1, 1945 these were used to determine the 5 year survival rate (Table III). Data on the 2 patients who died in the hospital were not included in Table III. Of the 37 remaining patients 2 could not be traced for 5 years after operation. The 3 year survival rates also are shown. However, these are not of great significance for this period of survival might be expected after palliative surgery. Such is not true for the 5 year group. A comparison of the 5 year survival rate with that in cases of nonobstructing annular type of lesion shows that for completely obstructing annular carcinoma of the descending colon and sigmoid the rate is approximately half that for the nonobstructing annular type of carcinoma. The 5 year survival rate in the cases of nonobstructing annular carcinoma of the descending colon and sigmoid was 51.7 per cent and that in cases of completely obstructing annular carcinoma was 25.7 per cent.

SUMMARY AND CONCLUSIONS

The 5 year survival rate in 37 cases of completely obstructing annular carcinoma of the descending colon and sigmoid in which resection was performed is compared with the 5 year survival rate in cases in which nonobstructing lesions had been treated surgically.

These rates were 25.7 per cent and 51.7 per cent, respectively.

The five factors which may contribute to the lowered 5 year survival rate are (1) damage to the intestinal wall with increased permeability and increased lymphatic absorption (2) hypertrophy of the musculature which produces a massaging and traumatizing action to the carcinoma at the site of obstruction (3) inflammatory swelling and edema which cause breakdown of any mechanical protective factor and of any protective forces elaborated by the host (4) the invasive property of the cancer cell whether it be motility or some lytic action which is facilitated by the effect of the factors just mentioned, and (5) the ileocecal valve which may produce a closed loop type of obstruction.

The size of the lesion is of no significance in prognosticating the presence of metastasis, and the volume (cubic centimeters) of malignant tissue is actually less in the cases of obstruction than in the cases in which no obstruction was present.

No correlation was found between the grade of the lesion and the incidence and degree of obstruction or between the duration of obstruction in days and the survival rate.

We realize of course, that this is a small series of cases on which to base any definitive conclusions but with the strict criteria for obstruction used namely, complete obstruction requiring a colostomy or cecostomy for decompression before removal of the lesion, the series would of necessity have to be small. Notwithstanding we do believe that such a difference in the 5 year survival rate in cases of obstructing and nonobstructing carcinoma of the descending colon and sigmoid 26 per cent in this series, is significant. This difference is not due to a difference in the grade of malignancy of obstructing carcinomas but rather apparently to the condition of the intestinal wall attending the complication of obstruction.

COMEDOMASTITIS

A Clinical and Pathologic Study of Data in 172 Cases

GEORGE I TICE, M.D. MALCOLM B DOCKERTY M.D., and
STUART W HARRINGTON M.D. F.A.C.S., Rochester Minnesota

COMEDOMASTITIS is a disease of the breast characterized by dilatation of the lactiferous ducts which are distended with inspissated grumous material that may be expressed from the cut ends of the ducts much as comedones are expressed from ordinary blackheads. It is a disease of the large ducts in contrast to chronic cystic mastitis which is a disease of the acini and ductules. Marked clinical similarity to mammary malignancy may be present when comedomastitis results in an indurated area of the breast which is fixed to the skin and is associated with a retracted nipple. Even the pathologic picture may be confused with that of carcinoma unless the true nature of the lesion is appreciated.

REVIEW OF LITERATURE

The use of the term 'comedomastitis' to describe this condition has gained limited acceptance (15, 19, 45, 57). Dilatation of the ducts has long been known to exist in chronic cystic mastitis and senile atrophy of the breast but Bloodgood (6-10) was the first to consider this type of lesion as a clinical and pathologic entity which he called 'varicocele tumor of the breast'. He noted that the condition was usually bilateral and that it was more common in women more than 45 years of age. Parity appeared to have little influence on the frequency of occurrence. He described dilated thick walled ducts which contained green brown milky or creamlike material of varying degrees of viscosity and consistency. Some times induration was so marked that the lesion looked felt and cut like carcinomatous tissue. He found the lesion in breasts that were otherwise normal, senile adenomatous cystic or malignant. However, he stated that the gross finding of ducts distended with grumous material militated against a diagnosis of mammary carcinoma.

Cheate (12) and Cheate and Cutler (14) expressed a belief that enlargement of ducts resulted from overgrowth of epithelium and excessive desquamation rather than from obstruction. They described (13, 14) conditions clinically similar to comedomastitis and saw dilated ducts with retained secretion in carcinomaous breasts. Adair and Bagg indicated that abnormal drainage from the breast was an important factor in production of cancer. Adair (2) found obstruction which was due to a localized growth of the lining epithelium of the ductules to abnormality of the nipple including inversion bivalving puckering adherence dwarfing and ulceration to fibrous scars across the lumina of ducts to cysts fibroadenoma or inflammation to desiccated desquamated ductal estuaries. Semb found dilatation of the milk ducts in association with fibroadenoma tosis which he stated predisposed to bacterial infection but he could demonstrate no connection between the occurrence of local purulent inflammation and the development of cancer. Handley described duct catarrh wherein plugs of epithelial debris marked the orifices of the milk ducts from which wormlike casts of material could be clinically expressed. There was thickening of the ducts as they converged on the nipple.

In breasts with cystic disease Lewis and Geschickter found ectasia of the ducts which sometimes were filled with material of putty like consistency. They attributed cystic disease to hormonal imbalance and observed that theelin produced similar changes in animals. Later Geschickter described 7 cases in which

titis, and in none of the cases of "cancer" could the source of the growth be traced to the comedomastitis. They concluded that the lesion complex was not primarily related to the proliferative and cystic lesions but that it might occur independently or in unison with the others.

Other authors have reported or described cases similar to those of comedomastitis (5, 11, 16 21-23, 28, 29, 32, 35, 40 42-44 49, 51 55, 57 58). It has been shown that those breasts which have produced large quantities of milk have larger ducts than poorly secreting or non-secreting glands (31). The effects of hormones on the breasts of animals have been summarized by Patey and Shimkin.

MATERIAL AND METHOD

The surgical and pathologic files of the Mayo Clinic were searched for the records of all cases in which the diagnosis of comedomastitis had been made for the years 1925 through 1942. Material which had been taken at mastectomy in 185 cases and at local mammary resection for comedomastitis in 19 cases and which had been preserved in 10 per cent solution of formalin was secured and studied. In cases in which bilateral mastectomy had been done with a different diagnosis for the lesions in the 2 breasts, the "uninvolved" breast still was reviewed with the idea of picking up minimal or early "comedo" changes. Size and distribution of the ducts were particularly noted although cysts abscesses fibrosis fibroadenoma, carcinoma and papilloma were also looked for. Ducts were often probed or laid open to be certain of their true character. As a rule, one block from each quadrant and one through the nipple of each of the whole breasts was taken so as to demonstrate typical areas of comedomastitis minimal areas and transition zones. When only a portion of the gland was available, one piece was chosen to show the typical pathologic picture. All blocks were placed in a fresh 10 per cent solution of formalin and slides were subsequently prepared by the freezing method and stained with hematoxylin and eosin.

For a better understanding of the condition those cases in which operation was performed solely for the relief of comedomastitis were

considered separately from the group wherein the main diagnosis was carcinoma or papilloma. The first group was represented by material from 144 whole breasts and 19 incomplete breasts in the second group material from 41 cases in which mastectomy had been performed was available for study.

PATHOLOGIC CONSIDERATIONS

The size of the involved breasts varied from enormous, fatty glands to shrivelled nubbins. The nipple was available for study in 143 breasts; it was abnormal in 31 breasts, with retraction or inversion in 28 and inflammation in 3. In 1 case the nipple had been surgically removed previously. Fifty-five contained palpable single masses and 16 multiple masses. Fifty-nine breasts were described as diffusely nodular granular cystic or shotty and 23 had localized thickening or nodularity. In only 2 were the dilated ducts noted as being palpable. Fixation of the mass to the skin, or to the nipple, was present 37 times. In 1, a draining sinus was present. In 5 abscesses were identified. Eight contained nodules typical of fibroadenoma and 1 contained a lesion which later proved to be fibrosarcoma. As this seemed to be entirely unrelated to the mastitis the case was included in the benign series.

After section of the gland the most striking feature noted was the presence of comedones which could be squeezed from the ducts like toothpaste from a tube. Although typically grumous, this material varied from an oily secretion to a thick dry form with the consistency of cheese (Fig. 1). The color was white, gray, yellow, green or brown. Many of the ducts were large and thick walled so that they stood out like pipestems, even after the secretion was expressed, but some would collapse to slits. The extent of the ectasia varied from distinct enlargements in scattered sites to markedly dilated cavities that honeycombed the gland. In 29 of the specimens only slight dilatation occurred. In the 96 in which moderate degrees of ectasia occurred, in 8 the ectasia was in scattered parts, in 27 it occurred beyond the nipple only and in 61 it occurred diffusely. In 19 breasts there were marked changes, with large ducts running from the ampulla to the periphery in all sectors. Six of

the excised portions of mammary tissue exhibited minimal to moderate and 2 marked dilatation.

Fibrosis was obvious in the atrophic type of breast in which sections were sometimes difficult to cut. In the fatty organs this was still evidenced by the increased density of the septa. Eighty-seven of the specimens contained macroscopic cysts varying from a minimum of 1 millimeter to 8 centimeters across.

The prominent and distinguishing features of the microscopic structure were the changes in the ducts and periductal tissues. The method of preparation frequently destroyed the retained secretion but where the secretion did persist it consisted of pink-staining amorphous, granular or cellular debris. At times fat laden phagocytes, inflammatory cells, and desquamated epithelial cells were found within the lumen. The distribution and degree of dilatation of the ducts as seen microscopically was, for the most part as indicated in the description of the gross appearance but differences did occur. Even when the ducts seemed diffusely distended a few usually remained almost normal in size and contour. In the most marked cases all ducts seen near the nipple were enlarged (Fig. 2). Some of those that were grossly affected only near the nipple or in scattered areas exhibited microscopic changes in the ductal and periductal tissues indicating diffuse disease. For the most part, the ducts near the nipple were irregular in outline and somewhat collapsed when the retained secretion was lost, but many of the peripheral ducts remained wide open as a result of fibrosis.

Aside from round cell infiltration associated with the lactiferous ducts and the two specimens in which moderately severe subepithelial inflammation had occurred, the nipples were microscopically normal. Although microscopic anatomic obstruction of the neck of the ducts was searched for none was found, except in the aforementioned cases in association with gross deformity.

The epithelium of the ducts near the nipple was normal, but with distention of the duct it thinned and the individual cells tended toward a cuboidal appearance. Occasional vacuolated cells could be found in most specimens.

In 6 of the cases there was an increased number of desquamated cells. In 9 additional cases these changes were present and were associated with a great increase in the number of vacuolated cells.

The peripheral ducts usually were lined by smaller cuboidal cells. The number of cell thicknesses was variable and ranged from 6 to 8 down to a single flattened layer or even to complete denudation (Fig. 3 a and b). The largest most distended ducts or those with the most periductal fibrosis tended to have fewer layers. Those with evidence of little periductal inflammation and minimal dilatation would often have normal epithelium while those with moderate inflammatory changes and distention had more variations in type. In 12 of the cases an increased proliferation was noted within the ducts, with the formation of masses of cells and tiny papillae with or without anastomosing branches. Some of the small ductules were occluded by this overgrowth but none of the epithelium could be called atypical. In isolated areas of the ductal wall of 9 of the specimens were found colostrum-like cells which were large, pale and round with slightly acidophilic cytoplasm and small dense nuclei. The epithelial layer was thickened by masses of these cells which encroached on or filled the lumen (Fig. 4, a and b).

A few of the breasts showed no evidence of periductal reaction to the retained secretion, but the great majority had responded with inflammatory changes which ranged from a slight amount of small round cell infiltration to acute abscess formation. The predominant and universally present type of cell was the lymphocyte. Large wandering cells and plasma cells could usually be identified. In some, chronic granulation tissue with proliferating endothelial cells and fibroblasts was seen. Subacute inflammatory changes which were found in 8 of the breasts were characterized by the presence of many plasma cells, an occasional giant cell and a few polymorphonuclear leukocytes (Fig. 5). Acute or subacute abscesses were identified microscopically in 5 of the cases. In 3 there were pseudotubercles, with giant cells and epithelioid cells. In 10 of the breasts a site of rupture of a duct was visualized invading the lumen by granulation tissue and

Fig. 1. Diffuse comedomastitis. The most marked changes are beneath the nipple.

exudate was apparent. Marked chronic inflammatory tissue surrounded these areas and was spread through the stroma. Fat laden phagocytes were present in the periductal tissues and in the lumen. The finding of hemosiderin laden histiocytes in the periductal tissues of 8 specimens suggested previous hemorrhage. Periductal fibrosis was often marked so that the ducts were surrounded by concentric rings of hyalin-appearing connective tissue. In these instances the epithelial lining was atrophic and the periductal lymphocytic infiltration was mild to moderate; the infiltrated tissue was separated from the lumen by wide bands of connective tissue.

Fig. 2. Cross section of a nipple. Note great dilatation of the ducts immediately beneath nipple. $\times 5$.

The stromal fibrosis was more evident in the small atrophic glands where it often caused squeezing and distortion of the remaining lobules of the breast. In others much of the stroma had been infiltrated with fat. In those breasts with evidence of moderate to severe inflammation, the infiltrate extended into the stroma and, in a few instances, the areolar and fibrous tissue of the entire organ was involved.

Usually in the lobules there was only insignificant round cell infiltration. Sometimes however the lobules were trapped in the inflammatory exudate which had spread from a nearby duct so that the tubules and acini appeared as scattered epithelial islands in a sea of lymphocytes, with the lobular structure being unrecognizable. Nineteen of the specimens contained scattered small lobules with fibrosis and a decrease in the epithelial elements. In one or two of these specimens the lobules approached normal but in most they were definitely atrophic. Early or mild proliferative changes, affecting both the epithelial

the excised portions of mammary tissue exhibited minimal to moderate and 2 marked dilatation.

Fibrosis was obvious in the atrophic type of breast in which sections were sometimes difficult to cut. In the fatty organs this was still evidenced by the increased density of the septa. Eighty-seven of the specimens contained macroscopic cysts varying from a minimum of 1 millimeter to 8 centimeters across.

The prominent and distinguishing features of the microscopic structure were the changes in the ducts and periductal tissues. The method of preparation frequently destroyed the retained secretion but where the secretion did persist, it consisted of pink-staining amorphous granular or cellular debris. At times fat laden phagocytes, inflammatory cells and desquamated epithelial cells were found within the lumen. The distribution and degree of dilatation of the ducts as seen microscopically was for the most part, as indicated in the description of the gross appearance but differences did occur. Even when the ducts seemed diffusely distended, a few usually remained almost normal in size and contour. In the most marked cases, all ducts seen near the nipple were enlarged (Fig. 2). Some of those that were grossly affected only near the nipple or in scattered areas exhibited microscopic changes in the ductal and periductal tissues indicating diffuse disease. For the most part the ducts near the nipple were irregular in outline and somewhat collapsed when the retained secretion was lost, but many of the peripheral ducts remained wide open as a result of fibrosis.

Aside from round cell infiltration associated with the lactiferous ducts and the two specimens in which moderately severe subepithelial inflammation had occurred, the nipples were microscopically normal. Although microscopic anatomic obstruction of the neck of the ducts was searched for none was found except in the aforementioned cases in association with gross deformity.

The epithelium of the ducts near the nipple was normal, but with distention of the duct it thinned and the individual cells tended toward a cuboidal appearance. Occasional vacuolated cells could be found in most specimens.

In 6 of the cases there was an increased number of desquamated cells. In 9 additional cases these changes were present and were associated with a great increase in the number of vacuolated cells.

The peripheral ducts usually were lined by smaller cuboidal cells. The number of cell thicknesses was variable and ranged from 6 to 8 down to a single flattened layer or even to complete denudation (Fig. 3 a and b). The largest, most distended ducts or those with the most periductal fibrosis tended to have fewer layers. Those with evidence of little periductal inflammation and minimal dilatation would often have normal epithelium while those with moderate inflammatory changes and distention had more variations in type. In 12 of the cases an increased proliferation was noted within the ducts, with the formation of masses of cells and tiny papillae with or without anastomosing branches. Some of the small ductules were occluded by this overgrowth but none of the epithelium could be called "atypical." In isolated areas of the ductal wall of 9 of the specimens were found colostrum-like cells which were large, pale and round, with slightly acidophilic cytoplasm and small dense nuclei. The epithelial layer was thickened by masses of these cells which encroached on, or filled the lumen (Fig. 4 a and b).

A few of the breasts showed no evidence of periductal reaction to the retained secretion but the great majority had responded with inflammatory changes which ranged from a slight amount of small round cell infiltration to acute abscess formation. The predominant and universally present type of cell was the lymphocyte. Large wandering cells and plasma cells could usually be identified. In some, chronic granulation tissue with proliferating endothelial cells and fibroblasts was seen. Subacute inflammatory changes which were found in 8 of the breasts were characterized by the presence of many plasma cells, an occasional giant cell and a few polymorphonuclear leukocytes (Fig. 5). Acute or subacute abscesses were identified microscopically in 5 of the cases. In 3 there were pseudotubercles, with giant cells and epithelioid cells. In 10 of the breasts a site of rupture of a duct was visualized invasion of the lumen by granulation tissue and

Fig 2. Cross section of a nipple. Note great dilatation of the ducts immediately beneath nipple $\times 5$

exudate was apparent. Marked chronic inflammatory tissue surrounded these areas and was spread through the stroma. Fat laden phagocytes were present in the periductal tissues and in the lumen. The finding of hemosiderin laden histiocytes in the periductal tissues of 8 specimens suggested previous hemorrhage. Periductal fibrosis was often marked so that the ducts were surrounded by concentric rings of hyalin appearing connective tissue. In these instances the epithelial lining was atrophic and the periductal lymphocytic infiltration was mild to moderate. The infiltrated tissue was separated from the lumen by wide bands of connective tissue.

The stromal fibrosis was more evident in the small atrophic glands where it often caused squeezing and distortion of the remaining lobules of the breast. In others much of the stroma had been infiltrated with fat. In those breasts with evidence of moderate to severe inflammation the infiltrate extended into the stroma and, in a few instances the areolar and fibrous tissue of the entire organ was involved.

Usually in the lobules there was only insignificant round cell infiltration. Sometimes however the lobules were trapped in the inflammatory exudate which had spread from a nearby duct so that the tubules and acini appeared as scattered epithelial islands in a sea of lymphocytes with the lobular structure being unrecognizable. Nineteen of the specimens contained scattered small lobules with fibrosis and a decrease in the epithelial elements. In one or two of these specimens the lobules approached normal but in most they were definitely atrophic. Early or mild proliferative changes, affecting both the epithe

lum and connective tissue in the lobules, were present in 35 of the breasts. Sometimes proliferation of the epithelial cells predominated to give extensive formation of new tubules and acinus-like structures. Occasionally the stroma was the more active of the two elements and the scattered compressed and irregular ductules or acini simulated infiltrating malignant tissue. The tubules sometimes showed small degrees of dilatation that did not correspond with the extent of ectasia in the larger ducts. These changes have been called adenofibrosis (54) 'mastodynia' (38) "blunt duct adenosis" (26) sclerosing adenosis (26) and mazoplasia (14). Not included were those specimens with pale-staining epithelium, but otherwise these changes were similar to those in fibroadenomatosis microcystica (48).

In 44 breasts, simple cysts with a lining of cuboidal or flattened epithelium were present. In 43 the cysts were associated with large pale staining columnar epithelial cells of the apocrine type giving the picture of Schimmelbusch's disease. For the most part, the cysts did not share in the inflammatory process that so often accompanied comedonasti-

tis. Occasionally there was fibrosis of the wall and a moderate amount of reaction and at times the inflammation had spread from the periductal tissues to include a cyst. Apocrine type of epithelium was also found in 22 of the breasts that did not contain macroscopic cysts. Such epithelium was not found in the ectatic ducts and hence was not considered as evidence of ductal hyperplasia even though papillae with anastomosing and interlacing branches were found within a cyst. The breasts in which cystic and apocrine changes occurred were referred to simply as those with cysts those with cysts and apocrine epithelium or those with apocrine epithelium but without cysts. These would include the cystic disease and adenosis of Geschickter diffuse papillary cystadenoma of Schimmelbusch diffuse nonencapsulated cystic adenomatosis of Bloodgood, fibroadenomatosis cystica of Semb and the cystiferous desquamative epithelial hyperplasia of Cheate and Cutler. The concurring fibroadenoma and fibrosarcoma were typical in appearance and there was no evidence of dilatation of the ducts within them.

During the course of the study it became evident that most of the diseased breasts fell

Fig. 4. a, left, Colostrum like cells found in an isolated area of the ductal epithelium. $\times 100$. b, Heaping up of the

colostrum-like cells so that the lumen of the duct is almost occluded. $\times 100$

into rather well defined groups, based entirely on the pathologic changes observed. Both the gross and the microscopic findings were evaluated in determining the correct place for each. The distribution of the lesions allowed for division of the lot into three groups. The designation focal was used when the disease was in one localized part or in scattered parts diffuse indicated involvement of the greater share of the duct system. Since the entire

breast had not been removed in 19 instances the extent of the disease could not be determined and these were called "sectional." The severity of the disease in the ducts formed the basis for subdividing each of these 3 groups into "early" and "advanced." The terms did not refer to the actual time the breast had been involved but indicated the degree of the changes in the breast. In "early" disease the periductal fibrosis was absent or minimal the

foreign body giant cells. $\times 66$. c, In this section is shown the granulomatous reaction with the formation of pseudotubercles. $\times 67$

periductal inflammation was minimal to mild (Fig. 6 a). In advanced disease the periductal fibrosis was moderate to marked, the periductal inflammation was moderate to marked, there was a large amount of retained secretion and the dilatation of the ducts was moderate to marked (Fig. 6 b and c).

Of the 19 biopsy specimens, 11 showed early stages of the disease and 8 showed advanced lesions. Three of the whole breasts were classified as early. These contained one or more areas of comedoma titis in which the changes in the ducts were slight. Only one could be called focal advanced, and it exhibited moderately severe ductal and periductal changes in a scattered area. The diffuse early group consisted of 53 breasts in which there was involvement of most of the ductal system but the changes present were minimal to mild. Only five breasts made up the diffuse advanced group; this group included those with the most widespread and most marked disease.

The majority of those specimens with focal or early comedoma titis or both exhibited cystic changes or apocrine epithelium, while the majority of those with marked evidence of diffuse advanced disease exhibited atrophic changes or early proliferation. Conversely, in the great majority of those specimens with atrophy or early proliferation there were advanced forms of comedoma titis, while in the majority of those with cysts or apocrine epithelium or both, early forms of comedoma titis were present.

The relation ship of the unusual pathologic findings to the type of comedoma titis present is of interest. As would be expected, the diffuse advanced group contained the greatest share of those breasts in which complications had occurred. These complications included rupture of the ducts, deposition of hemosiderin about the ducts, subacute inflammation, abscess formation, presence of pseudotubercles and plasma cell mastitis. In contrast the findings indicative of secretory activity, which were excess desquamation or vacuolation beneath the nipple and the presence of colostrum like cells were confined with two ex-

ceptions to the early group. Surprisingly enough, the percentage of specimens in the focal groups which showed secretory activity was higher than that in the "diffuse" groups. The incidence of hyperplasia within the duct did not vary with the stage of the disease. Hyperplasia was not found in any breast in which atrophic or early proliferative changes were present in the lobules.

CLINICAL FEATURES

Bilateral involvement of the breasts, whether associated with comedoma titis or some other disease, was common. Although a total of 163 benign breasts were examined, there were but 110 patients. Each breast was considered as a separate pathologic entity and such viewpoint has been continued in the presentation of the clinical features. Twenty-seven of the women underwent simultaneous or consecutive bilateral amputation for comedoma titis. Thirteen had clinical mastitis in the opposite breast at the time of examination and 6 of the 13 had undergone excision of a portion of that breast. Nine patients had undergone mastectomy for some type of benign lesion, 2 had undergone mastectomy for papilloma, 10 had undergone radical mastectomy for cancer and 1 had undergone mastectomy elsewhere by means of application of a "paste" for suspected malignancy. Three others had had comedoma titis associated with cancer in the opposite breast. Sixty-five had had a clinically normal breast on the side opposite that of the operation.

Patient. In the local early group had had more trouble with other forms of disease of the breast than had those in the other groups, even though fewer of them had bilateral comedoma titis, while in contrast patients in the diffuse advanced group more frequently had had bilateral comedoma titis and less frequently had suffered from other forms of disease of the breast. The absence of previous cancer in this latter group may be significant.

All of the patients in this series were white women. Their ages ranged from 28 to 75 years at the time the breasts were removed, with an average age of 45 years. The ages by groups were as follows: sectional early, 43.3 years; sectional advanced, 43.3 years; focal early,

Fig. 6 a, Early comedomastitis with mild periductal reaction although the ducts are considerably dilated. Note also the increase in fibrosis of the stroma. $\times 27$ b, Advanced comedomastitis with marked ductal distention, periductal inflammation and periductal fibrosis. This spec-

imen also shows the typical appearance of the retained secretion. $\times 27$ c, In this specimen of advanced comedomastitis is clearly demonstrated the heavy rings of connective tissue that sometimes form about the dilated ducts. $\times 18$.

47.9 years focal advanced 53 years diffuse early 44.5 years and diffuse advanced 43.6 years. These figures do not permit the assumption that the disease progresses in degree and severity with increasing age. Fifty three of the breasts were from postmenopausal women while 30 were from women who gave a history of menstrual irregularities which were usually associated with the menopause. These irregularities were especially frequent in those with focal early disease. Thirty three of the breasts had never been subjected to the stimulus of pregnancy and lactation. Only 4 nulliparas had advanced disease. This was in contrast to the high incidence of milder forms of disease in nulliparas and indicates that the stimulative changes associated with pregnancy and lactation may predispose to the development of advanced comedomastitis. Although there was a higher incidence of familial cancer in patients with the early stages of the disease no significance was attached to this finding.

Symptoms An attempt was made to determine the principal symptom and its duration. If one judges the onset and duration of the disease from the time of onset of the principal symptom one finds that those patients

with the diffuse advanced disease had a shorter clinical course than those with other forms. It may be that comedomastitis in itself is relatively silent until the inflammation becomes severe enough to draw attention while those breasts with cysts are likely to have lumps or pain which draw attention before the less noticeable comedomastitis has developed fully.

A lump in the breast was described in a higher proportion of those patients with advanced disease than in those with early disease. The term 'discomfort' was used to include any unpleasant or painful sensation from itching to excruciating pain whether constant intermittent or cyclic. Because of this interpretation this symptom was the most common and it was present in a great majority of patients. The occurrence of discharge in 33.3 per cent of those in the diffuse advanced group appears significantly larger than that of 21.8 per cent for the diffuse early and 27.9 per cent for the focal early groups. When a purulent type of discharge was present it was described as gray green orange or brown. More than half of those patients with a history of abnormality of the nipple had marked comedomastitis. Of those with diffuse advanced disease 6.7 per cent had noticed a

change in the nipple. Of the 6 with congenital inversion of the nipple 4 had severe disease throughout. The majority of nipple changes were in those breasts in which there were atrophic or early proliferative changes.

No particular emphasis was placed on a history of injury to the breast although 6 of the women did give this information. Not one of the patients directly related her difficulty to the trauma. No determination of the number of lactations or of the duration of each could be made from the case records. Abnormalities of lactation were noted in 10.4 per cent of the breasts and in more than half of these breasts advanced disease was noted. Of those with prolongation of secretion the discharge remained milky in one but became purulent in the others. Frequent episodes of nonpuerperal mastitis could be expected in this disease and the incidence was 14.1 per cent. It was the most common in those patients with the diffuse advanced disease although the difference was not as great as might be anticipated.

Signs. The term 'nodularity' was used to apply to those breasts described as granular or shotty or as giving evidence of mastitis or thickening. The breasts so designated made up the largest single group, being especially frequent in association with diffuse early comedomastitis. The diffuse advanced group exhibited a great tendency to have a single mass and every breast of this class had some palpable physical finding. In only 2 cases were palpable ducts described as such. There was but little difference in the total number of cases, type of discharge or distribution as to groups previously defined between the cases in which a discharge was expressed from the nipple at the time of examination and those in which a discharge had been noted by the patient. More nipple abnormalities were found by the medical examiner than had been complained of by the patient, but the same trends as to distribution in the three groups were present. More than half of the deformities occurred in association with diffuse advanced stages of disease. Conversely in 37.8 per cent of patients with diffuse advanced disease lesions of the nipple were present.

Induration, edema, redness, or heat were the signs of inflammation although the occurrence

of induration alone was not considered sufficient evidence. These findings could be expected with marked comedomastitis and in more than half of the instances they were associated with severe disease. Whenever fixation of a mass to the skin or nipple is determined on examination, malignancy must be considered and the occurrence of such fixation in 22.7 per cent of the entire series was remarkable. The rate was even higher (33.3 per cent) when diffuse advanced comedomastitis alone was considered. No detailed endocrine studies were carried out. In 14 cases some hormonal imbalance was indicated when routine examinations disclosed diabetes mellitus, hypogonadism, hirsutism, myxedema, low basal metabolism without myxedema and hyperthyroidism. Sixty-four of the breasts were from women exhibiting some type of pelvic abnormality.

Those breasts in which some kind of complication developed caused few symptoms or signs that were at variance with those to be expected from the groups to which they belonged. In 3 out of 4 cases of severe comedomastitis with congenital inversion of the nipple multiple complications occurred. In those cases in which there was ductal hemorrhoidrosis no increase in frequency of bloody discharge occurred. In only 2 of the 5 cases in which microscopic abscesses occurred were clinical signs of inflammation present. Only 3 of those breasts that showed changes suggestive of secretory activity had spontaneous discharge from the nipple and another had a serous secretion on examination. These changes were not necessarily residua of lactation as the colostrum like cells appeared in the breast of one nulliparous single woman. The 2 breasts with subepithelial inflammation were from women with sore nipples.

Diagnosis and treatment. Often the diagnosis of a breast lesion on clinical grounds is expressed in a broad inclusive term and a specific diagnosis must await the pathologist's examination of tissue. The diagnosis of comedomastitis was made preoperatively but twenty-one times although the condition was probably recognized more often and it was included in 64 other cases under the term 'mastitis'. That comedomastitis may simulate malignancy was only partly illustrated by the

13 cases in which a diagnosis of carcinoma had been made. Many of those called "tumors" (24 cases) and Paget's disease' (2 cases) were considered "suspicious."

All of the breasts were removed surgically. In 19 of the cases simple excision was considered sufficient to eradicate the involved parts or to prove benignancy. The great majority of the operations consisted of simple mastectomy but in 2 cases the lesion imitated carcinoma so closely that radical mastectomy was performed.

COMMENT

Retention of secretion dilatation of the ductal system and periductal mastitis have been shown to be the principal pathologic characteristics of comedomastitis. It appears that the process starts with stasis of the ductal contents with resultant distention. As the more liquid part of the secretion is absorbed the contents become concentrated and viscid. With decomposition or infection irritative substances are produced and inflammation of the ductal walls and periductal tissues results. Complications may develop that lead to abscess formation or to the extensive subacute inflammation of plasma cell mastitis. A subsidence of the more acute phases is followed by fibrosis and hyalinization of the periductal connective tissues so that the irritant medium is effectively walled off from sensitive tissues. A breast with relatively mild changes could be fairly rapidly changed into one showing marked disease by the introduction of infection or by the erosion and rupture of a duct so as to allow the escape of highly irritant secretion into the areolar tissue. One would expect that the ducts which are the site of extensive periductal mastitis would progress to the stage of fibrosis and hyalinization but in some instances inflammation is resolved with few traces remaining and the breasts return to a stage that is represented by that of the diffuse early group. If for some reason the factor that produces dilatation of the ducts ceases to operate and drainage of the system takes place a diffuse ectasia might be wholly or partially relieved so that the breast would fit the criteria for the focal early classification or the tissues might even re-

turn to normal. There is no reason to believe that some of the breasts considered in the present study had not been through this cycle in whole or in part. Some of those in the focal early category which were associated with a history of purulent discharge, nonpuerperal mastitis or abscess may have had a severe inflammation that left little trace. However, in those with the pathologic changes of severe chronic inflammation resolution could hardly be expected to occur.

The sequence of events as just described seems logical and all stages can be seen. To determine the cause of the stasis is more difficult. It may result from obstruction of the ductal system and retention of normal secretion from increased formation of secretion in excess of the amount that the normal mechanism can eliminate or from a combination of the two. Endocrine imbalance and abnormalities of development may account for the process.

In the cases of comedomastitis in this study there was evidence of obstruction of the mammary ducts. In 6 cases congenital inversion seemed sufficient to impair drainage. These women were unable to nurse and pregnancy increased the chance of trouble. Apparently the remaining 22 patients with inversion or retraction had acquired deformities which were a result of the inflammatory process within or around the ducts rather than the cause, although such deformity once acquired would tend to interfere with drainage and increase the stasis already present. The one breast with absence of the nipple was diseased before ablation was done. Inflammation beneath the nipple could cause stasis, but, once again, the stasis is more likely to be an effect. The incidence of some type of abnormality of the nipple in diffuse advanced comedomastitis was 37.8 per cent and it may be that the majority of the lesions were made worse by the deformity even though the deformity was not the primary cause.

The scarring subsequent to trauma could impede outflow, but no definite connection could be shown in the present study. Inflammatory tissue may occlude the lumina or produce scarring in the stroma of sufficient degree to cause obstruction. Of the 23 instances of nonpuerperal mastitis only 3 definitely pre-

ceded the comedonastitis while the remaining 20 were more likely a result of the disease and were to be expected in the natural course of comedonastitis. The 3 breasts associated with a history of lactation abscess and the 5 in which a tender lump had developed in association with lactation may have been the sites of inflammatory or sclerotic changes sufficient to block the ductal system.

While the ducts near the nipple would be the logical site for obstruction a similar effect might be obtained by blockage of many smaller ducts distally. Such blockage might account for some of the scattered focal lesions and might even be responsible for a few lesions of the diffuse types. Expanding lesions of the breast, especially cysts and also fibroadenoma and fibrosarcoma could block adjacent and distally located ducts by compression. Intraductal tumors will frequently produce dilatation of the duct distally with retention of secretion and periductal mastitis but the instances of hyperplasia found in this series were mild and seemed insufficient to be causal.

Theoretically extramammary pressure from improperly fitted or improperly worn garments could obstruct the normal outflow of the ducts. Large pendulous breasts drag and may distort the ductal system. We have no evidence that either of these was a factor.

Excessive secretion or desquamation will overburden the normal capacity of the ductal system to discharge its contents. Both occur during and immediately after lactation and lactation does apparently have some influence on the development of comedonastitis. Few nulliparae have severe disease. The poor drainage associated with inverted nipples has already been considered. The 5 patients in whom a tender lump developed in the breast either during lactation or immediately after its cessation may have had inflammation, overproduction of secretion or both. In 4 breasts a prolongation of the secretory activity occurred after nursing had ended.

The presence of colostrum like cells in the peripheral ducts and vacuolated or desquamating epithelium or both behind the nipple was probably indicative of secretory activity although further studies and special staining would be necessary to prove this. Similar find-

ings have been described in association with chronic cystic mastitis and with a disease similar to comedonastitis (14 27 33 52). In the present study the secretory action if any, did not seem to increase the stasis as stasis occurred more frequently in the mild forms of the disease. The inflammation associated with development of severe ductal lesions could obscure or destroy the evidences of secretory activity but these evidences seemed more closely associated with cystic disease or apocrine epithelioma.

There were evidences of cellular activity in response to irritation in almost all of the specimens examined as most of them showed areas of thickening of the epithelium and some increase in shedding. In the 12 breasts that showed excessive hyperplasia there was an increased amount of desquamation. Infection such as a chronic lactation mastitis might have initiated the triad of stasis dilatation and periductal inflammation by distention of the duct with exudate as well as by obstruction of the normal outflow. However when the inflammatory exudate was a response to the irritants of decomposing secretion it could not be considered as the primary cause although the invasion of the lumen of the duct would have augmented the severity of the disease already present.

Atrophic changes in the breast resulting in ectasia of the ducts and retention of secretion are an etiologic factor in older women. Some authors (9 27) have said that these degenerative changes are primarily responsible for a disease similar to comedonastitis, but others (26 37 54) have found this disease in the breasts of younger women which have not undergone atrophic changes and which have presented a variable pathologic picture as was observed in the present study.

The excellent work that has been done on the hormonal influences in diseases of the breast indicates that endocrine glands may control the development of any type of lesions in the breast. In this series there was inadequate evidence of endocrine dysfunction but the occurrence of comedonastitis at the time of life when endocrine disorders are common may be an indication that it is secondary to some type of abnormal hormonal stimulation. The dil-

tation of the ductal system that is produced in animals by the administration of estrin is similar to that which occurs in the early stages of comedomastitis

RELATIONSHIP OF COMEDOMASTITIS TO OTHER DISEASES

Chronic cystic mastitis Comedomastitis frequently is inseparably bound to chronic cystic mastitis in the present study. 144 of the 163 breasts contained macroscopic cysts, apocrine epithelium or early proliferative changes in the lobules. Often the diagnosis of chronic cystic comedomastitis was made to express the true situation. Indeed in many of the early cases the comedomastitis was overshadowed by the cystic and apocrine changes. The presence of cystic disease in the breast may explain why there is a lower average age and a shorter clinical course in cases of advanced comedomastitis than in cases of early comedomastitis when one might expect from the pathologic picture the reverse to be true. Chronic cystic mastitis may also account for the presence of masses discharge from the nipple retraction or inflammation in the breast which is the site of mild scattered comedomastitis. A truer picture of what can be expected clinically from comedomastitis might be obtained from a study of the diffuse advanced group alone.

The intimate relationship of comedomastitis and chronic cystic mastitis may be exploited on the basis of etiology. The stasis of secretion in the ductal system may be the inciting factor in production of either. Many authors have observed dilatation of the ductal system in cystic disease and the cysts themselves are usually considered as enlargements of the smaller tubules or acini while comedomastitis involves the larger ones. Why one breast produces cysts and another dilated ducts is not known although the influence of senile involution or residual postlactation ductal enlargement or inflammation would tend to give comedomastitis. The localized changes of the disease can be secondary to the production of cysts which compress adjacent ducts. Time may prove that the two types are responses to different hormones.

Mammary carcinoma The etiologic significance of stasis of secretion within the ductal system in the production of neoplasm within the breast has been stressed (2-4, 14, 18, 25, 30, 34, 57). It was stated that the breakdown products of this material were irritant and that they led to epithelial proliferation. The work (56) showing that oleic acid can serve as an activator for mild carcinogens is suggestive. Analysis of retained secretion by Lepper and Weaver showed it to be principally fat with some breakdown products of protein while Adair and Bagg found lactic and butyric acids in thick creamy discharges from the nipple. Most of these investigators have stated that chronic cystic mastitis is precancerous, and the work carried out in studies on animals corroborates this viewpoint (50).

Others (9, 26, 27, 54) said that there was no relationship between the occurrence of lesions similar to comedomastitis and the development of malignancy. When they described cases of marked retention of secretion they found no associated cancer even though cancer was found in another portion of the same breast. In most of those breasts in which neoplastic changes occurred the dilatation of the ducts with retention of secretion was considered incidental to malignant change.

In our series while we were procuring specimens of comedomastitis every case in which that diagnosis had been made was included, and it was found that 23 of the breasts contained concurrent papilloma and 18 contained carcinoma. The presence of the tumor was the only differential point in the gross pathologic appearance. Although the comedomastitis was less advanced and the incidence of hyperplasia was much higher when neoplasia was associated the changes in the ductal system were of the same order as in the benign series. Breasts which contained cysts or apocrine epithelium or both formed the large majority of the cancerous group. The possibility that most carcinomas associated with comedomastitis arise from the ductal system as comedocarcinoma was suggested by the finding of comedocarcinoma in 5 cases and comedo areas in 5 of the infiltrating growths.

The tendency to bilateral disease of the breast was present although it was less definite

in the cases in which papilloma was present. One patient had bilateral comedomastitis and papilloma and another had bilateral comedomastitis and carcinoma. In 3 patients, the remaining breast was removed for benign comedomastitis subsequent to a radical operation for comedomastitis and cancer of the opposite breast. All of the patients with bilateral disease of the breast had cysts or apocrine epithelium or both. Although the youngest patient aged 16 years was in the group with papilloma, the average age in these cases of malignant disease was slightly higher than that in the benign series; however the difference was not as great as one might have expected if the comedomastitis had been primary and the neoplasia had supervened. The duration of the clinical disease indicated that the disease in those patients with neoplasms had a slightly longer time in which to develop; however this determination was made from the time of onset of the principal symptom which was usually associated with the tumor. The incidence of nulliparity is much higher in cases of comedomastitis associated with papilloma than it is in cases of comedomastitis associated with carcinoma. In turn the incidence of nulliparity in cases of comedomastitis associated with carcinoma is slightly higher than it is in cases of benign comedomastitis. There was more familial carcinoma in those patients with neoplasia. The clinical features were predominantly those of the presence of the tumor mass. Little evidence of the comedomastitis was present. There was nothing to indicate that the comedomastitis antedated the neoplasia. Indeed, the reverse may have been true because neoplastic changes may have caused obstruction of the ducts and an increase in desquamation.

In comedomastitis, retention of secretion occurred in the most extensive degree, and while the stages of the disease were not definitely fixed, they were a good indication of the degree of stasis and of the amount of irritation and inflammation that occurred. Instead of the most advanced forms of the disease being found in association with neoplastic changes, the reverse was true. The irritant quality of the secretion was obvious from the amount of inflammatory infiltrate and the epithelial

thickening that occurred to some extent, in all but the cases of earliest comedomastitis, but hyperplasia sufficient to give cell massing and branching forms was infrequent in the benign cases and occurred then only in those breasts that presented other evidence of a growth stimulus in the form of cystic changes or apocrine epithelium. The hyperplasia that was found in association with neoplasia was much more exuberant and much more common than that which was not associated with neoplasia. There was no correlation between the stage of the comedomastitis and the extent or incidence of this overgrowth. There were fewer breasts with atrophic or early proliferative changes in the carcinoma series than in the series with nonmalignant lesions.

No additional cases of early carcinoma arising in comedomastitis were found. Two cases that were originally considered carcinoma could not be verified as such in our section. None of the malignant areas could be traced directly to origin in a focus of comedomastitis. Indeed there was no indication that progression or prolongation of comedomastitis led to an increase in hyperplasia or neoplasia or both. It may be that the ductal lining is resistant to the proliferative stimulus as Geschickter suggested. Apparently neoplasia, when it occurs along with comedomastitis, has a different inciting agent from that of comedomastitis.

Plasma cell mastitis. Ewing (24) commented on plasma cell mastitis that 'the main gross anatomic feature is the presence of many such thickened ducts which are filled with puriform material and may extend over a large segment or the whole of the breast. In other descriptions (1 19 20 39 41 45) the presence of large ducts with retained secretion has also been given as an important feature of this disease. Others (27 33 57) have stated that there is a close relationship between plasma cell mastitis and comedomastitis or a disease similar to comedomastitis.

Examples can be found that show every stage in the development of plasma cell mastitis from comedomastitis. In some of the cases of comedomastitis subacute or chronic inflammation about the ducts, presumably due to the leakage of ductal content into sensitive periductal tissues may be evident. In these

cases may be found giant cells foam cells and plasma cells. One patient with bilateral breast disease illustrated the transition very well. In the breast on one side there was typical cell mastitis, while in the opposite breast there was comedomastitis which varied from mildness in some areas to severity in other areas as evidenced by the presence of granulation tissue which contained plasma cells foam cells and foreign body giant cells. In other breasts of the series subacute inflammation and even pseudotubercles were present, but these lesions were considered those of comedomastitis.

It cannot be stated from this study that plasma cell mastitis is invariably the result of comedomastitis but it does seem to be a stage in the same disease process.

Traumatic fat necrosis Traumatic fat necrosis as described by Lee and Adair may be related to or identical with some forms of comedomastitis. There is similarity in appearance. Foote and Stewart expressed a belief that some changes associated with atasis and periductal mastitis fit the picture of traumatic fat necrosis. Cole stated that fat necrosis may be identical with plasma cell mastitis if there is minimal liquefaction of fat. Rodman and Ingleby stated that plasma cell mastitis infected galactocoele, traumatic fat necrosis and lactation mastitis are all parts of the same process.

Fibroadenoma There was no indication that fibroadenoma had direct connection with any of the cases of comedomastitis aside from the action of any tumor in obstructing adjacent ducts. One case has been reported (37) in which fibroadenoma associated with dilated ducts was found in a breast similarly affected.

Other diseases Cases described as chronic galactorrhea chronic lactation mastitis and so forth may be variations of cases of comedomastitis in some instances, but they do not appear to be identical.

CONCLUSIONS

1 Comedomastitis is a disease characterized by stasis of secretion dilatation of the ducts and periductal mastitis.

2 The clinical features of the disease vary widely but the disease may be suspected in the presence of a history of abnormality of

lactation nonpuerperal mastitis, discharge from the nipple or abnormality of the nipple. On examination the lesion may closely simulate carcinoma because of the indurated, fixed mass and retracted nipples.

3 Comedomastitis usually is associated with chronic cystic mastitis which may overshadow it clinically.

4 Neoplasia, although it occasionally occurs in the same breast as does comedomastitis, is probably not related to the latter etiologically. By simple obstruction of the mammary ducts such neoplastic changes may at times produce a focal comedomastitis.

5 Plasma cell mastitis is probably a form of comedomastitis.

RESULTS OF TREATMENT OF CARCINOMA OF THE OVARY WITH DATA ON THE AGE INCIDENCE OF THIS DISEASE

JOSEPH H MARKS M D and MARTIN H WITTENBORG M D., Boston, Massachusetts

A REVIEW of the literature on malignant epithelial tumors of the ovary leaves some doubt as to the value of roentgen therapy in this disease. Most of the previously reported series of cases show little if any benefit as a result of such therapy. Most authors have recommended that x ray treatments be given as a palliative measure in the more advanced cases. They have admitted that the dosage given to many of the patients was less than optimum as judged by present standards.

It is unfortunate that in the majority of cases the disease is of an insidious nature and that in most hospitals the operability rate is less than 40 per cent. It is also unfortunate that even for those patients judged operable at the time of exploration the cure rate is distressingly low. It appears obvious, therefore that the proper treatment for carcinoma of the ovary has not yet been found.

Walter Bachman and Harris in 1941 reviewed the literature up to that time and reported a series of cases from Mount Sinai Hospital in New York. Of 63 cases of all stages of the disease in which surgery was the only form of treatment 24 per cent were alive at the end of 1 year and only 6.3 per cent at the end of 5 years. Of 31 patients treated by means of surgery followed by adequate roentgen therapy 87 per cent were alive at 1 year and 29 per cent at 5 years. At first glance one may be inclined to discount their figures since the group receiving roentgen therapy contained a smaller number of advanced cases than did the group having surgery alone. However their figures may be further subdivided to show that for the cases judged operable and having surgery only the 5 year salvage rate was 21 per cent whereas the operable group in which patients had surgery plus roentgen therapy showed a salvage rate

of 40 per cent. Of the advanced cases in which patients had surgery alone none was alive at 5 years whereas similar cases in which patients received postoperative x ray treatment showed 18 per cent survivals at 5 years. It thus appears that the chance for survival was definitely increased when postoperative x ray treatments were given.

The same authors believed that histological grading played a minor role in prognosis and that the extent of the disease was of much greater importance. They concluded that x ray therapy was of real value in the treatment of ovarian cancer and that the surgeon should not take too great risks in an attempt to remove the last fragments of diseased tissue but should instead rely on postoperative roentgen therapy.

Other authors (3, 4, 8, 9) have reported series of 100 or more cases with 5 year survival rates which vary from about 15 to 35 per cent. Within these groups of cases there has undoubtedly been some variation in the type of material seen in the interpretation of the histology and in the vigor with which postoperative radiation was given. The highest survival rate appears to be that of Lynch who reported 35.5 per cent in a group of 62 proved cases alive and well at 5 years. He refers to 2 cases in which operation was known to be incomplete but the patients lived 13 and 17 years following x ray therapy. He also reports one proved recurrence after 13 years, and calls attention to several cases of long duration in which patients had little or no x ray therapy but in whom peritoneal implants apparently regressed following removal of the primary tumors. Pemberton in 1940 believed that the operation should be as radical as circumstances would permit and should be followed by x ray treatment. Taylor and Greeley in 1942 were able to show little or no improvement in their

survival curve by giving postoperative radiation but believed it probable that in an occasional case x ray therapy was an essential factor in producing cure.

The group of cases which we wish to report shows a salvage rate which is no higher than that already reported by other authors. We do believe however that adequate x ray therapy may be of very real value to these patients and that it may occasionally be curative. We therefore find ourselves in partial disagreement with Meigs (4, 5, 6) who believes that x ray therapy has never cured patients but it has helped to make them live longer.

We wish to report the series of patients seen in the department of roentgenology of the New England Deaconess Hospital during the 10 year period beginning in June 1936. The series consists of 76 patients, 57 of whom have now been followed to death. Of the original group 14 were alive more than 5 years after their first operation and treatment but 3 of the 14 have since died of their disease and one is alive at 5½ years with recurrent disease. Not all of the patients have as yet had an opportunity to live 5 years after treatment but the 5 year survival rate calculated by the method of Nathanson and Welch is 21 per cent.

It comes as no surprise to find that the 2 patients having stage 1 disease are alive and apparently well 7½ and 8 years following treatment. Of much greater interest are those who survived more than 5 years in spite of the fact that when first seen their disease was too extensive to permit complete surgical removal.

Such a patient was first operated upon in another hospital where large masses had been found in both ovaries. Multiple smaller nodules were scattered through the pelvis and in the general peritoneal cavity where there was a large amount of exudate. The fluid had been removed and a biopsy done. Histological examination had shown papillary cystadenocarcinoma. She was then seen by Dr. E. M. Daland who referred her to us for x ray therapy. She was given 1900 roentgens to each of two anterior and two posterior pelvic ports with 1500 roentgens to each of two upper abdominal ports. Ports measured 15 by 15

centimeters and all treatments were given at 400 kilovolts with other factors as noted below. About 6 weeks later she was again operated upon. On this occasion there was no evidence of disease outside the pelvis and there was no abnormal amount of peritoneal fluid. Ovarian tumors were still present but were smaller than at the time of the first operation, and were removed. Another period of 6 weeks was allowed to pass and she was then given a second series of x ray treatments. These treatments were given through the six ports first used and with the same factors. The last treatment was given on September 30, 1938. Since that time she has been well except for gradually increasing evidence of radiation damage to the skin and subcutaneous tissues. In May 1946 it was necessary to excise an area over the sacrum and replace it with a graft. There is still no evidence of recurrent ovarian tumor.

Six other patients in the group of 14 survivors have received equally large amounts of treatment to the pelvis but in only 2 others has treatment been given to the upper abdomen. Their skin and subcutaneous tissues show varying degrees of atrophy and telangiectasia but only the one has so far required excision and graft. No patient in the surviving group has had less than 1800 roentgens to each of four pelvic ports.

In each case an effort was made to plan the treatment so that all diseased tissue would be included within the ports. If operation had shown the disease to be confined within the pelvis the treatments were given through two anterior and two posterior pelvic ports. In all except very small women the ports measured 15 centimeters square in order to be sure to include the entire pelvic cavity. In previously untreated patients the ports were usually directed straight through the pelvis. Except in the aforementioned case a second or third course of treatments was not given unless there was objective evidence of residual or recurrent disease. If such disease became manifest in the form of a discrete mass, the subsequent treatment was usually directed toward it through ports which would crossfire the mass, and when such a mass seemed to be confined to one side of the pelvis it was usually

Fig. 1. Series incidence of 74 cases of carcinoma of the ovary

treated through anterior posterior, and lateral ports

If operation had shown the tumor to involve the general peritoneal cavity as well as the pelvis treatments were planned for four pelvic ports and two upper abdominal ports, provided the general condition of the patient would permit such an extended series. In such cases the four pelvic ports were treated first and the upper abdominal ports were the ones which were omitted if it became necessary to stop the series before the entire plan could be carried out.

When the disease was far advanced and exudate was the chief problem treatments were usually given through four anterior abdominal ports. Such ports usually measured 15 centimeters square and were frequently tilted slightly toward the midline in order to conform to the contour of the abdomen.

The original plan of treatment almost all ways called for 1800 roentgens (measured in air) per port whether or not the beams were crossfired but modifications of the plan were frequently required as the series progressed. Treatments were given at 400 kilovolts with 50 centimeter target to skin distance and with a filter of 0.9 millimeter tin, 0.25 millimeter copper and 1.0 millimeter aluminum. The normal daily dose was 300 roentgens to a single port, and treatments were given daily except Sundays.

The group of patients in whom long term survival was not secured were frequently benefited in a palliative sense by x radiation. Illustrative of that group was a woman who had been operated upon elsewhere 7 years previously because of carcinoma of the ovary

Fig. 2. Death rate for cancer of all types in Massachusetts for 1930. The curve quickly goes off the page unless a semi-logarithmic scale is used.

When seen by us there was a hard mass which extended upward to the level of the umbilicus and there was a large amount of peritoneal exudate. Paracentesis had been necessary every 10 to 14 days during the recent past because of the rapid production of the fluid. She was given 1800 roentgens to each of four anterior abdominal ports and did not require paracentesis thereafter. The mass persisted in spite of a second series of treatments which was given 7 months later through four pelvic ports. She died 14 months after her first series of treatments.

AGE INCIDENCE

During the course of study of this group of cases we wished to know whether or not the age of the patients was in any way unusual. Figure 1 was therefore constructed in order to show the number of patients afflicted during each decade of life. At first glance the chart did not appear in any way unusual, and it was obvious that the largest number of patients were in their sixth decade when the diagnosis was made. The number of persons under 30 years of age was approximately the

Fig. 3. Age specific incidence of 494 cases of carcinoma of the ovary

same as the number of those over 70 years old.

The chart was then corrected in order to take into account the number of females living in Massachusetts in each decade of life. The greatest frequency for the disease was again in the sixth decade and although the incidence over age 70 was then approximately eight times the incidence under age 30 it was still only about one third the incidence of the sixth decade. The series was admittedly small for any study of age incidence but the apparent decrease in rate after age 60 was of considerable interest, since the age specific death rate (and incidence) for most types of cancer rises sharply with advancing years. The age specific death rate for cancer of all types in the United States for 1940 was 61 per 100,000 persons living between the ages of 35 and 44 years, 369 per 100,000 between 55 and 64 years, and 1,183 per 100,000 for persons over 75 years of age (9). These rates are almost identical with those computed for Massachusetts for 1930 (1). Organ specific rates have also been computed from Massachusetts data for cancer of the breast, uterus,

urinary bladder, skin and buccal cavity. In each case the rate rises steadily with advancing years although the rate of rise varies independently for each organ.

We are not aware of previously published data concerning the age specific incidence of carcinoma of the ovary. The records of 430 histologically proved cases have been consulted in addition to those of the 74 proved cases already noted. The age recorded is that at the time when the patient was first seen because of the ovarian cancer. A total of 135 cases are from the Palmer Memorial unit of the New England Deaconess Hospital, 89 from the Peter Bent Brigham Hospital, 154 are from the Massachusetts General Hospital and 126 from the Pondville State Hospital for Cancer. The figures for the Massachusetts General Hospital and the Pondville State Hospital were kindly obtained for us by Drs. J. A. Meigs and Langdon Parsons. Figure 3 shows the incidence by decades for the group.

SUMMARIES OF CASES SURVIVING 5 YEARS

CASE 2. Panhysterectomy was performed in a patient aged 53 years. A tumor which involved primarily the right ovary and extended a loop of bowel was resected followed by x-ray treatment consisting of 1800 roentgens through 4 pelvic ports. Patient was well 7 years.

CASE 2. Panhysterectomy was done in a patient of 34 years. Implants were noted throughout the pelvis and abdomen. She was given 1800 roentgens through 4 pelvic and 2 upper abdominal ports. She was well 6 years.

CASE 3. Patient aged 30 years had an exploratory laparotomy elsewhere 3 months previously. Mass now extends to umbilicus. At second operation tumor was found adherent to both lateral walls of the pelvis. Gross disease known to be left behind where it enveloped ureter. She was given 800 roentgens through 2 large pelvic ports. Eighteen months later she was given 3000 roentgens through 4 pelvic ports because of a tender mass on left. Eight months later she was given 1500 roentgens through 4 pelvic ports plus 1500 roentgens through a left lateral port. Seven years after first treatment she began to have trouble with a rectal stricture evidently due to irradiation. Colostomy was done 1 year later. She died 9 years after the first operation.

CASE 4. Patient aged 48 years had had a panhysterectomy elsewhere in 1936 for presumed benign cystadenomas. In 1937, a mass adherent to the bladder, sigmoid and pelvic walls was excised. The mass is now histologically malignant. X-ray therapy consisted of 3000 roentgens through 4 pelvic ports. Patient was well 9 years.

CASE 5 Patient aged 45 years had had a panhysterectomy. It was found that a tumor had invaded the uterus and was adherent to the pelvic wall. She was given 1100 roentgens through 4 pelvic ports. Patient was well 6 years.

CASE 6 Patient aged 39 years had been operated upon elsewhere in 1929 for a malignant papillary tumor of the ovary. Roentgen therapy had been given elsewhere in 1932. Patient was first seen at New England Deaconess Hospital in 1939 when she presented a tender mass in right side of pelvis. She was given 1800 roentgens through 4 pelvic ports. Two years later a colostomy was done elsewhere because of obstruction of the colon. There was an extensive tumor in the pelvis but none was seen in the upper abdomen. She was given another course of 1500 roentgens through 4 pelvic ports. She died 15 years after the first operation. 5 years after the first treatment by us.

CASE 7 Patient aged 43 years was operated upon elsewhere 7 years previously for papillary adenocarcinoma. When seen at New England Deaconess Hospital she presented a mass with exudate. Examination of the fluid revealed tumor cells. She was given 1800 roentgens through 4 abdominal ports. No further fluid was found but the mass persisted. Seven months later she was given 1800 roentgens through 4 pelvic ports. She died 7 months later. 8 years after operation.

CASE 8 Patient aged 59 years had had a panhysterectomy. A tumor adherent to the pelvic wall and rectum was found. Roentgen therapy consisted of 1800 roentgens through 4 pelvic ports. She was well 7 years.

CASE 9 Patient aged 53 years was given 1800 roentgens through 4 pelvic ports following panhysterectomy. She was well 8 years.

CASE 10 Patient aged 34 years had had an exploratory laparotomy but only biopsy specimens were taken. Implants were noted throughout the pelvis. She was given 1800 roentgens through 2 large pelvic ports. Three months later she was given 1800 roentgens through 4 abdominal ports. Five months later she showed persistent mass in the pelvis and was given 1500 roentgens through 4 pelvic ports plus 600 roentgens through 2 lateral ports. One year after first operation panhysterectomy was accomplished in spite of dense adhesions. Histological examination of tissue showed malignant papillary cystadenoma with radiation reaction. Patient was well 7 years after operation.

CASE 11 Patient aged 31 years was given 1800 roentgens through 4 pelvic ports after a left oophorectomy. She was well 8 years.

CASE 12 Patient aged 43 years had had an exploratory laparotomy elsewhere which revealed large masses in each ovary and smaller nodules elsewhere. Abundant fluid was present. Biopsy was done. She was given 1800 roentgens through 4 pelvic ports plus 1500 roentgens through 2 upper abdominal ports. At second operation masses were removed followed by the administration of 2000 roentgens through 4

pelvic ports plus 1500 roentgens through 2 upper abdominal ports. A radiation ulcer over sacrum was excised $7\frac{1}{2}$ years later. No evidence of residual tumor was found.

CASE 13 Patient aged 60 years had had a panhysterectomy. A mass was adherent to the pelvic wall. She was given 1800 roentgens through 4 pelvic ports. Treatment was repeated $4\frac{1}{2}$ years later because of the presence of a mass in right side of the pelvis. She was alive but with residual disease at $5\frac{1}{2}$ years.

CASE 14 Patient aged 39 years had had a panhysterectomy. Multiple implants were noted in the pelvis. She was given 1800 roentgens through 4 pelvic ports. Treatment was repeated 4 months later. She was well 9 years.

CONCLUSIONS

We believe that x ray therapy should be employed in all cases of carcinoma of the ovary that it is excellent insurance post-operatively even when the surgeon believes that all disease has been removed and that it may occasionally result in cure even in advanced stages of the disease.

We believe that the surgeon should not take too great risk in his attempt to remove the last fragments of diseased tissue but that he should remove the easily accessible masses and then rely on x ray therapy in adequate dosage and through whatever ports may be necessary to cover the involved areas.

X ray therapy may bring about gratifying palliation even when cure is not obtained. It often gives relief of pain and causes a retardation of the production of peritoneal and pleural fluids.

The age specific incidence of cancer of the ovary is unlike that of most other types of malignant epithelial tumors since it falls after the sixth decade.

STREPTOMYCIN IN THE SURGERY OF PULMONARY TUBERCULOSIS

JAMES D. MURPHY M.D. F.A.C.S. Oteen, North Carolina

THE medical sections of the Veterans Administration the Army and the Navy have been conducting a co-operative study of the bacteriostatic action of streptomycin on the tubercle bacillus. This study has presented American medicine with a unique opportunity. Never before has such a wealth of clinical material and trained medical personnel been immediately available for research on a new therapeutic agent.

The surgical divisions of the 47 participating study units were asked to determine whether streptomycin provides any protection against postoperative spread or reactivations and against the development of empyema in patients subjected to thoracoplasty and pulmonary resection for tuberculosis.

The program was initiated in January 1947. After that date every alternate patient subjected to thoracoplasty and every patient undergoing lobectomy or pneumonectomy was given streptomycin as a protective agent. It was felt that the use of controls in resection cases could not be justified under present conditions. The experience of leading clinics in this country had demonstrated that the mortality and morbidity rate following such procedures was so high as to be almost prohibitive. Six hundred resections for tuberculosis have been reported in the American literature since 1933. Five hundred and twenty of these have been performed since 1943. The total mortality rate in this group was 25 per cent. Empyema followed in 12 per cent of the operations and bronchopleural fistula occurred in 8 per cent. It was considered that these reports offered a sufficient background of experience with which to compare the streptomycin treated patients. If the drug were of value it would seem mandatory to use it in every patient undergoing resection in an effort to brighten this rather gloomy picture.

From the Department of Surgery, U.S. Veterans Administration Hospital, Oteen, N. C.

Thoracoplasty on the other hand has become standardized by several generations of thoracic surgeons and in recent years has been accompanied by few complications. The number of spreads or reactivations reported in series from the larger thoracic surgical centers has varied between 3 and 6 per cent with empyema a rare complication. The use of controls was considered essential to the study.

In the beginning 2.0 grams of streptomycin per day were given by intramuscular injection divided into 5 doses. On October 15, 1947 the standard daily dose was reduced to 1.0 gram divided into 2 doses of 0.5 gram each at 12 hour intervals. This reduction in dosage was made as a result of experience gained in the larger study of pulmonary and extrapulmonary tuberculosis of which this surgical investigation constituted a part. It was desired also to avoid, as far as possible the development of resistance to the drug. Resistance had been shown to develop rather uniformly after 6 to 8 weeks of treatment. Under both regimens the drug was administered for 1 week before and 2 weeks after each operation. Since the usual interval between thoracoplasty stages was 3 weeks and the number of stages per patient averaged 3, continuous administration of streptomycin for 9 weeks has been the rule in the thoracoplasty series.

The operating surgeons in each of the member groups were designated or approved by the Veterans Administration Central Office. A further condition of the study was that the indications for operation should not vary from those in use at the respective clinics before streptomycin was employed.

An analysis of the individual reports from the contributing groups indicated that thoracoplasty operations had been performed in 28 hospitals. The number of patients operated upon at each hospital varied from 1 to 99. In both the treated and control groups, 1,347 stages of thoracoplasty were performed.

In the group of streptomycin treated patients 699 operations were performed upon 258 patients. Postoperative spreads or reactions resulted in 14, the majority of which were actually reactivations of pre-existing disease. Fifty per cent of the 14 occurred after the first stage. Thus spreads followed thoracoplasty in 2 per cent of the operations in patients treated either with 2.0 grams or 1.0 gram of streptomycin daily. In this group there were 8 wound infections or 1.1 per cent.

In the group of control or untreated patients there were 249 who underwent 648 operations. Among these there were 36 spreads or reactions reported. Wound infection occurred following 16 operations. Expressed in terms of per cent, spreads occurred in 5.6 per cent and wound infections in 2.4 per cent. In all respects except for the use of streptomycin, these groups were handled in a similar manner.

A reduction in the occurrence of spreads from 5.6 to 2.0 per cent by virtue of streptomycin protection in a consecutive series of 1347 thoracoplasty stages would seem a logical conclusion to be drawn from this study. If correct it certainly is of statistical significance. Analysis of the reports from the individual hospitals however indicate that in some of the larger centers, no such discrepancy between the groups of treated and untreated patients occurred. Some of those clinics were able to demonstrate that in the years prior to the discovery of streptomycin postoperative spreads had been held to a comparable figure.

There remains, however, a definite impression that streptomycin will make it possible to accept for operation many patients in whom the disease is too widespread or of too unstable a character to permit a thoracoplasty without its protection.

These facts were considered by the entire Conference¹ and a decision was reached to discontinue the streptomycin study insofar as it pertained to thoracoplasties. The consensus significant but that other factors such as techniques and in preoperative and postoperative care as reported by some member groups

¹Fifth Veterans Administration Streptomycin Conference, meeting in Chicago, Ill., April 15-18, 1948.

TABLE I.—COMPLICATIONS IN PULMONARY EXCISIONS TREATED WITH STREPTOMYCIN

	No. of patients	Spread	Bronchopleural fistula	Empyema	Wound infection	Deaths	
						Operative	Nonoperative
Lobectomy Treated 2.0 grams	34						
Treated 1.0 gram	43		3	2	0	0	1
Pneumonectomy Treated grams	80					1	
Treated gram	3				3		0
Total	160		3	2	3	1	0

might have influenced the results. It was agreed to permit each surgeon to continue the use of streptomycin in cases which in his judgment were questionable risks but in which the operation was necessary if the disease was to be controlled.

In the pulmonary resection group the results in patients operated upon with streptomycin protection were so superior to all those previously reported as to leave little room for doubt as to its value.

There were 129 resections performed: 77 lobectomies and 52 pneumonectomies. Sixty three of these patients were given 2.0 grams of streptomycin daily, divided into 5 doses; 66 were given 1.0 gram daily, divided into 2 doses. The results as shown in Table I indicate that the 1.0 gram is as efficacious as the 2.0 gram dose.

Fifty per cent of the patients have had a postoperative follow up of from 6 to 14 months. It is far too early to make other than a preliminary estimate of sputum conversion, but the figures reported indicate that concentrated specimens of sputa are negative to date in 73 per cent of these patients. There were postoperative spreads following 4 operations or in 3.1 per cent. One of these was of questionable character. Bronchopleural fistulas followed 5.7 per cent of the operations and empyema 4.0 per cent. There were 5 operative and 1 nonoperative deaths, a mortality rate of 4.5 per cent.

A reduction of the mortality rate accompanying lobectomy or pneumonectomy for

tuberculosis from 25 per cent, as reported in the immediate pre-streptomycin era, to 4.5 per cent in a large series of streptomycin treated patients is of tremendous significance. The reduction in occurrence of postoperative empyema from 12 per cent to 4 per cent is also dramatic. While other factors pertaining to anesthesia, surgical technique, and postoperative care may have aided in these results the fact seems unquestionably established that streptomycin has made resection for pulmonary tuberculosis feasible and reasonably safe.

In addition to the thoracoplasty and pulmonary resection groups, there were reported 8 open pneumonolyses 8 decortications 10 extrapleural pneumonolyses with lucite ball plombage and 12 cavernostomy closures in all of which streptomycin was used as prophylaxis. There were no spreads or other serious complications reported among these patients. The number of operations reported from any one unit was not large enough to be of statistical significance. The favorable results so far reported however indicate that the use of streptomycin may be extended to any thoracic surgical operation for tuberculosis, in which the possibility of spread, empyema, or fistula presents a threat to the success of the surgery.

DISCUSSION

This study seems to indicate that streptomycin has a protective action against spreads following thoracoplasty for tuberculosis. The operation of thoracoplasty however had become so standardized and the complications so few in the pre streptomycin era that this fact is difficult to establish unequivocally. Since the development of resistance to the drug is common after 6 weeks of treatment, it was felt that the degree of protection obtained was not of sufficient value to warrant its routine use. If a resection should be required at a later date the resistant patient would be at a distinct disadvantage since there is experimental evidence which suggests that treatment in a

resistant patient may be injurious. The majority of participating surgeons at the Conference were of the opinion that thoracoplasty can be performed by virtue of streptomycin protection on a few patients who would have been rejected because of the exudative character of their disease if the drug were not available.

There was unanimous agreement that the use of 10 gram of streptomycin daily for 1 week before and for 2 weeks after resection should be continued without the use of alternate controls. The reduction in mortality rate and in the frequency of occurrence of postoperative spreads empyemas and bronchopleural fistulas offers apparently incontrovertible evidence of the protective action of streptomycin in pulmonary resections for tuberculosis.

CONCLUSIONS

1 The results of a co-operative study concerning the protective action of streptomycin in 1,347 thoracoplasty stages and 129 pulmonary resections for tuberculosis are presented.

2 Streptomycin should not be given to the routine thoracoplasty patient but should be reserved for the occasional borderline risk patient in whom the disease is more widespread and more exudative in character than is usually considered suitable for surgery.

3 The use of streptomycin before and after operation in every pulmonary resection for tuberculosis is considered mandatory.

NOTE.—The information contained in the report of "Streptomycin in Surgery of Pulmonary Tuberculosis" represents the combined efforts of a large group. The accomplishment of these data could not have been accomplished without the unselfish co-operation of bacteriologists, internists, and surgeons, guided by expert statisticians.

Since Dr. Murphy was actively engaged in this project and had a significant personal series, he was asked to prepare the combined report.

This endeavor may well serve as a model for future combined research projects.

THE LUMBOSACRAL ARTICULATION

A Roentgenologic and Clinical Study with Special Reference to Narrow Disc and Lower Lumbar Displacement

ERNEST A. BRAV M.D., F.A.C.S., HOWARD A. MOLTER, M.D. and
WENDELL J. NEWCOMB M.D., Louisville, Kentucky

SINCE the early investigations of Goldthwait on the anatomy of the lumbosacral articulation in its relationship to low back and sciatic pain, numerous observers have recorded their findings which have emphasized the importance of this anatomic area in patients with these complaints. The studies of Von Lackum revealed the vulnerability of the lumbosacral area to trauma and degenerative change. Danforth and Wilson described the relationship between the lower lumbar nerves the intervertebral foramina the lumbosacral facets and the lumbosacral disc in the etiology of sciatic pain. Ayers reported the frequency of narrowed fifth lumbar intervertebral disc in patients presenting the sciatic syndrome. Williams expressed the opinion that the fifth lumbar disc was narrow in the majority of cases of sciatica and frequently in so called lumbago. Badgley, reporting a large series of patients with sciatic pain noted narrowing of the fifth lumbar disc in 57 per cent. All of these and many other observers felt that the disc narrowing was due to developmental traumatic and degenerative changes and that there was frequently associated displacement of the lumbosacral articular facets, with degenerative changes in the cartilage of the facets and narrowing of the intervertebral foramina. Ferguson however denies any relationship between narrow lumbosacral disc and the incidence of sciatic pain. Barr and Mixter state that a narrow lumbosacral interspace occurs about as frequently as other congenital abnormalities and should be considered as an incidental finding unless there is associated sclerosis or spur formation. Willis noted narrow disc in only 7.6 per cent of a series of patients with back and leg pain. Some writers described congenital narrowing of the disc while others attributed such obser-

vations to the presence of transitional vertebrae, the immature disc being mistaken for the true lumbosacral disc. Posterior protrusion of the disc, noted very early by Goldthwait and receiving widespread attention following the studies of Schmorl has been associated by many writers with the narrowed appearance of the disc as noted on the roentgenogram.

Anterior displacement of the fifth lumbar vertebra on the sacrum, usually associated with a defect in the interarticular portion of the neural arch has been well described by Neugebauer Junghanns Meyer Burgdorff, and many others. An excellent résumé by Chandler emphasizes that the cause of the cleft in the neural arch and of the forward displacement is as yet undetermined. Numerous observers have recorded the relationship between this condition and the development of low back and sciatic pain. Spondylolysis spondylolisthesis and potential spondylolisthesis are the terms used to designate a defect in the arch without forward slipping. Pseudo-spondylolisthesis is meant to convey forward displacement without defect in the neural arch and presumably due to anomalous articular facets or developmental abnormality in the arch of the fifth lumbar vertebra characterized by prolongation without interarticular defect.

More recently a condition of posterior displacement of the fifth lumbar vertebra on the sacrum so called reversed spondylolisthesis has been described by Smith Johnson, Williams Ferguson, and Haggart. These observers have noted the condition to exist frequently in patients with low back and sciatic pain and consider it a common lesion associated with anomalous development or degenerative change of the lumbosacral articular facets and often with narrowed lumbosacral disc.

Fig. 1. Schematic drawing of lumbosacral articulation. a, left, Usual relationship fifth lumbar and sacrum. b, right, Anterior displacement fifth lumbar vertebra with defect in neural arch.

The existence of this condition has however been vigorously denied by Willis on the basis of anatomical studies. He believes that the appearance on the roentgenogram is always due to the larger anteroposterior diameter of the fifth lumbar vertebra which creates on the film the optical illusion that it is posteriorly displaced on the sacrum. In skeletons, in 66 per cent of a series of 50 cases the diameter of the fifth lumbar was greater than the sacrum and in the remainder the measurements were equal. Willis feels that this is an anatomic variation and of no clinical significance. His views are shared by many clinical observers so that the existence of this entity remains controversial.

PURPOSE

In view of the continued difference of opinion relating to the importance of narrowed fifth lumbar disc and displaced fifth lumbar vertebra in the etiology of backache and sciatic pain, a study of a large series of roentgenograms was made with the purpose of establishing the incidence of these conditions. The group of patients whose roentgenograms were reviewed presented themselves for study chiefly because of back and leg complaints. There was, however, a relatively small number whose lumbosacral films were made not for backache but because of pelvic and abdom-

inal conditions vague extremity complaints and general disorders in which bone changes were suspected. Only one requirement was imposed—satisfactory anteroposterior and lateral lumbosacral films with a spot lateral in which the central rays passed directly through the lumbosacral joint. Five hundred such films were examined and the authors knew nothing about the reasons for roentgenographic study so that there were included both cases with back and leg pain and also a group with neither of these symptoms.

After determination of the incidence of narrowed lumbosacral disc and displaced fifth (and fourth) lumbar vertebrae the patients showing these changes on the roentgenograms were studied clinically to determine their principal complaints and important physical findings in the hope that this would throw some light on the importance of these roentgenographic changes. One hundred eighty-one cases were so studied. For comparison the clinical findings of the 319 patients whose films showed no displacement or narrow disc were also reviewed.

ROENTGENOLOGIC STUDY

The method of investigation of the true lateral roentgenograms is demonstrated diagrammatically in Figures 1 and 2. The anterior and posterior fourth lumbar disc measurements are designated by *AC* and *BD* respectively while these measurements for the fifth lumbar disc are represented by *EG* and *FH*. The anteroposterior diameters of the fifth lumbar and first sacral segments are measured respectively as *EF* and *GH*. Anterior displacement of the fifth lumbar vertebra measured at the posterior border is represented by *H H* whereas posterior displacement measured at the posterior border is *HHI*. In a previous article one of the authors (EAB) in the study of a series of roentgenograms of backache and control cases established an arbitrary minimum normal posterior fifth lumbar disc measurement as 5 millimeters. In this series all fourth or fifth lumbar posterior disc measurements less than 5 millimeters were considered narrow. Other observations from the true lateral views were the incidence of lumbosacral arthritis flattening of the lumbar spine, and

increased lumbar lordosis. Defects in fifth lumbar neural arch were observed and recorded.

In the anteroposterior lumbosacral films, transitional lower lumbar vertebrae were not ed together with other lumbosacral anomalies such as separate neural arch and spina bifida occulta. Immature horizontal or grossly abnormal lumbosacral facets were recorded in their relationship to fifth lumbar displacement. When a transitional lower lumbar vertebra was observed on the anteroposterior film care was taken to avoid measuring the transitional disc on the lateral view as the lumbosacral disc. When a sacral vertebra was *completely* lumbarized, the sixth lumbar disc was considered the lumbosacral. When a fifth lumbar vertebra was *completely* sacralized the fourth lumbar disc was considered the lumbosacral. In cases of *partial* lumbarization or sacralization, the disc immediately above the transitional vertebra was considered to be the lumbosacral. Although we did not have films of the complete spine and there may have been occasional error due to uncertainty as to which vertebra was the first lumbar it is felt that the error was minimal and certainly in no case was a transitional lower lumbar disc recorded as a narrow lumbosacral disc. The authors are furthermore well aware of the obvious lack of precision in the measurement of roentgenograms especially since there is always some slight difference in positioning and technique. However, it is felt that this lack of precision is well distributed in the large series and from the practical point of view can be disregarded in the interpretation of the roentgenologic findings.

Statistical Study of Roentgenograms

Narrow disc Of the five hundred roentgenograms there was definite narrowing of the fifth lumbar disc at the posterior margin in 131 (26.4%). The fourth lumbar disc was narrowed posteriorly in 18 (3.6%). The latter was associated with narrow fifth lumbar disc in 13 (2.6%).

The relative size of the fourth and fifth lumbar discs was studied. In the case of the *anterior* disc measurements the fourth lumbar was greater than the fifth in 184 (36.8%), it was less than the fifth in 256 (51.2%) and the

Fig. 2. Schematic drawing of lumbosacral articulation. a, left, Posterior displacement fifth lumbar vertebra and narrowed fifth lumbar disc; b, right, posterior displacement fourth lumbar vertebra.

measurements were the same in 60 (12.0%). In the case of the *posterior* disc measurements the fourth lumbar was greater than the fifth in 388 (77.6%), it was less than the fifth in 54 (10.8%), and the measurements were the same in 58 (11.6%).

Figure 3 shows the relative size of the fourth and fifth lumbar disc measurements. On the average, AC is somewhat less than EG but BD is considerably greater than FH . This would tend to show that there is a greater strain placed at the lumbosacral joint than in the region of the fourth lumbar articulation and might be one of the factors in the greater incidence at this point of strain, degenerative change, narrowed intervertebral foramina and

Fig. 3. Schematic drawing of lumbosacral articulation showing difference in fourth and fifth lumbar disc measurements and possible relationship to the frequency of lumbosacral pain. $AC < EG$ $BD > FH$ $AC:BD$ 2.5:1 $EG:FH$ 3.4:1

possibly posterior disc protrusion. In support of this hypothesis an average of the fourth and fifth lumbar disc measurements in the series shows that the relationship between AC and BD is 2.5 to 1 whereas the relationship between EG and FH is 3.4 to 1.

Displacement of Fifth Lumbar Vertebra

Displacement of the fifth lumbar vertebra occurred in this series in 76 (15.2%). Of these cases 32 (42.3%) were associated with narrow fifth lumbar disc.

Posterior displacement of the fifth lumbar occurred in 51 (10.2%). Of these 24 (43.1%) were associated with narrow disc. Anterior displacement of the fifth lumbar occurred in 25 (5.0%) and of these 8 (32.0%) were associated with narrow disc.

Anterior and posterior displacements were measured at both the anterior and posterior edges. In this series the average anterior displacement of the fifth lumbar vertebra at the anterior edge was 5.0 millimeters (L 16 S 2) while at the posterior edge it was 5.4 millimeters (L 14 S 2). In the case of posterior displacement of the fifth lumbar the average posterior displacement at the anterior edge was 2.2 millimeters (L 5 S 0) while at the posterior edge it was 4.6 millimeters (L 8 S 2).

Anteroposterior diameters. In considering the general question of displacement of the fifth lumbar vertebra, the relative depth of the fifth lumbar and first sacral segment was studied. In the entire series the anteroposterior diameter of the fifth lumbar was greater than that of the first sacral in 236 (47.2%) while it was less than the first sacral in 112 (22.4%). The measurements were the same in 152 (30.4%).

In cases showing posterior displacement of the fifth lumbar vertebra the diameter of this vertebra was greater than that of the first sacral in 47 (92.2%) less than the first sacral in none, and the same in 4 (7.8%).

In cases showing anterior displacement of the fifth lumbar vertebra the diameter of this vertebra was greater than the first sacral in 6 (24.0%) less than the first sacral in 14 (56.0%) and the same in 5 (20.0%).

It will be noted that in posterior and anterior displacement of the fifth lumbar vertebra,

there is a reversal of the relative number of cases in which the anteroposterior diameter of the fifth lumbar is greater than that of the first sacral. In the cases with posterior displacement the percentage of these cases is approximately twice that of the entire series, whereas in anterior displacement it is approximately half that percentage.

Apparent cause of displacement. Because it has been suggested that difference in anteroposterior diameters of the fifth lumbar and first sacral segments might account for the appearance of posterior displacement (and also presumably for some cases of apparent anterior displacement) each film showing anterior or posterior displacement was carefully evaluated from this point of view. Only the posterior edges were used in this evaluation because measurement of displacement at the anterior edge is extremely inaccurate and it has been shown by Ferguson that there is anterior slipping and compensatory increase in anteroposterior diameter of the first sacral segment as a result of the abnormal pressure on the anterior sacral edge in spondylolisthesis.

Comparison was made between the difference in anteroposterior diameters of the fifth lumbar and first sacral segments and the amount of displacement as measured at the posterior edge of these segments. If the difference in diameters was exactly the same as the amount of displacement it was assumed that the appearance of slipping was due to the difference in diameters alone. If there was no difference in diameters the amount of displacement was assumed to be a true forward or backward slipping. If there was a difference of diameters but this was not as great as the amount of displacement, it was assumed that the displacement was due to a combination of difference in diameters and true forward or backward slipping.

In cases with posterior displacement the difference in diameters alone could account for the apparent displacement in 10 (19.6%). Posterior slipping alone was the apparent cause in 4 (7.8%) while a combination of the two factors was noted in 37 (72.6%).

In cases with anterior displacement the difference in diameters alone was the apparent cause in none. Anterior slipping alone was re-

Fig 4 Roentgenogram of anterior displacement fifth lumbar vertebra. Lateral view showing defect in neural arch

Fig 5 Anterior displacement fifth lumbar vertebra. Lateral view with no defect in neural arch. Oblique views also showed no defect

sponsible in 11 (44 %) while a combination of the two factors was noted in 14 (56 %) in stances

Fifth Lumbar Arch Defects

Since it is a common observation that there is almost always a defect in the interarticular portion of the fifth lumbar neural arch to account for anterior displacement while no such logical explanation can be given for posterior displacement the presence of such defects was observed and recorded (Fig.4) It is also conceivable that either anterior or posterior displacement might be due to anomalies or degenerative changes in the lumbosacral articular facets.

In the 25 cases of anterior displacement of the fifth lumbar vertebra, a definite defect in the neural arch was noted in 21 (84%) In none of these cases was anything unusual not

ed in the lumbosacral facets In 3 cases (12%) no break in the arch was observed but since no oblique views of the lumbosacral area were available in these cases it must be assumed that the defect might have been revealed by such views In only 1 case (4%) was there definite anterior displacement with no defect on any of the lumbosacral views despite repeated examination (Fig 5) This case did show immature lumbosacral facets

The anterior edge of the sacrum was studied in these cases of anterior displacement to note the presence of anterior hipping and spur formation It was felt that this factor might account for the increased percentage of cases in this group which showed the anteroposterior diameter of the first sacral segment to be greater than that of the fifth lumbar In 11 cases (44%) definite anterior spur formation was noted

Fig. 6. Posterior displacement of fourth lumbar vertebra with lateral view. There is lateral displacement of the second, third and fourth lumbar vertebrae.

In the cases of posterior displacement the cause was investigated from the appearance of the lumbosacral articular facets. In only 5 cases (10%) was there any suggestion from the roentgenogram that immature horizontal or completely internal-external facet might be the basic factor in the displacement.

Fourth Lumbar Displacement

Displacement of the fourth lumbar vertebra was noted posteriorly in 13 (26%) (Fig. 6) and anteriorly in 2 (4%). This was noted in association with fifth lumbar displacement in 8 (16%). The average anterior displacement at the anterior edge was 4 millimeters (L 5 S 3) and at the posterior edge was 4 millimeters (L 5 S 3). The average posterior displacement at the anterior edge was 2.2 millimeters (L 5 S 0) and at the posterior edge was 3.8 millimeters (L 5 S 3). The anterior cases were

Fig. 7. Anterior displacement of fourth lumbar vertebra with lateral view. There is lateral displacement of the second, third and fourth lumbar vertebrae.

accompanied by a definite break in the neural arch of the fourth lumbar vertebra.

Lumbosacral Region

Encephalitis. The total cases with lumbosacral anomalies consisting of transitional lower lumbar vertebrae, spina bifida occulta, defective neural arch, an immature articular facet were 15 (33%).

Transitional lower lumbar vertebrae were noted in 60 (135%). Of these cases there was an associated narrow lumbosacral disc (narrow immature transitional disc) in only 9 (15%). Complete lumbarization was noted in 1 (4%) and partial lumbarization in 35 (76%). Complete sacralization was present in 7 (14%) and partial sacralization in 1 (2%).

The other lumbosacral anomalies were noted in 112 (224%) and of this number 16 (14%) were associated with transitionals and 30

(26.8%) were associated with narrow fifth lumbar disc.

Arthritis Definite arthritic changes were noted at the lumbosacral articulation in 36 (7.2%). Of these 25 (70%) were associated with narrow fifth lumbar disc (Fig. 7).

Of 181 cases with narrow disc or lower lumbar displacement 27 (15.0%) had lumbosacral arthritis. This was present in only 2.8% of the other cases in the series.

Curve There was definite loss of the normal lumbar curve in 62 (12.4%). It is noteworthy that in the 51 cases of posterior displacement of the fifth lumbar vertebra the lumbar curve was flat in 16 (31.4%) whereas in anterior displacement it was flat in only 1 case (4%). Of the cases with flat lumbar spine there was associated narrowed fifth lumbar disc in 21 (34.0%).

Of 181 cases of narrow disc or displacement, 27 (15.0%) had flat lumbar spine. This was present in 11.0% of the other cases.

Increased lumbar lordosis was noted in 16 (3.2%). In the cases with anterior displacement of the fifth lumbar vertebra increased lordosis was present in 3 (12.0%) while in posterior displacement it was noted in none. Of the cases with increased lumbar lordosis there was associated narrowed fifth lumbar disc in 4 (25%).

Of 181 cases of narrow disc or displacement 8 (4.4%) had increased lordosis. In the other cases it was found in 2.5 per cent.

CLINICAL STATISTICS

The clinical records of the patients were examined after the roentgenographic findings had been recorded. Most of the patients had been seen by the senior author in consultation and his clinical findings noted on the records.

There were 181 patients (36.2%) whose roentgenograms showed narrow fifth lumbar disc displacement of the fourth or fifth lumbar vertebra or a combination of these findings. There were 319 patients (63.8%) whose films showed none of these changes. The latter will be referred to as the control group.

The patients were chiefly adult males. There were 176 (97.3%) between the ages of 21 and 60. Only 1 patient was under 21 years and 4 were over 60 years.

Fig. 8. Posterior displacement fifth lumbar vertebra, lateral view. The slight difference in anteroposterior diameters of the fifth lumbar and first sacral segments only partially accounts for the amount of posterior displacement.

Incidence of Back Pain

Of the entire series of 500 patients, backache was present in 405 (81.0%), there was associated leg pain in 145 (29.0%) and neither of these complaints was recorded in 95 (19.0%). In no case was there leg pain alone, although in a few the complaint of hip pain was interpreted as backache.

Of the 181 patients with narrow disc or lower lumbar displacement backache was present in 153 (84.5%) and there was associated radiating leg pain in 53 (29.2%). In 28 (15.5%) neither of these complaints was present.

In the control group backache was present in 252 patients (79%), there was associated leg pain in 92 (29%) and in 67 (21%) neither complaint was noted.

Conversely there were in the entire series 260 patients with back pain alone. Of these

Of 132 cases with narrow fifth lumbar disc 23 (17.4%) had no complaints. Of 51 cases with posterior displacement of the fifth lumbar 3 (5.9%) were without back or leg pain and of 25 cases of anterior displacement 2 (8%) did not make these complaints. Of 15 cases of displacement of the fourth lumbar vertebra all presented symptoms of backache with or without leg pain.

Diagnosis It is noteworthy that in 20 patients (13.6%) no definite orthopedic diagnosis could be made to account for the patient's back and leg complaints. In the control group, there was failure in diagnosis in 67 (26.6%).

Of the 153 patients with such complaints 61 (40.5%) were thought to have some form of arthritic change, 50 (32.7%) were thought to have a localized muscular or ligamentous strain and 16 (10.4%) were diagnosed as a low lumbar posterior disc protrusion. Other diagnoses were made in 6 (3.9%). There were 4 cases in which the complaints were thought to be due to an old spinal osteochondritis, one was due to a secondary lesion from carcinoma of the prostate and one was due to simple contusion.

In the control group 41 (16.3%) were diagnosed as arthritis, 106 (42.1%) as strain, 28 (11.1%) as protruded disc and other diagnoses were 10 (3.9%). A comparison of the clinical findings noted in the group with narrow disc or displacement and in the control group is represented in Table II.

Disc series Because a narrowed lower lumbar disc on the roentgenogram is often associated by authors with posterior protrusion of such a disc and the production of clinical signs, the cases in which protruded lower lumbar intervertebral disc had been diagnosed were studied with this point in mind. There were 44 patients on whom this clinical diagnosis had been made. Of these, 33 (75%) were diagnosed by clinical methods and 11 (25%) were confirmed by surgical exploration.

In this group the incidence of narrowed lower lumbar disc as noted on true lateral roentgenograms was 13 (30.0%). Of the cases confirmed by operation 9 revealed protrusion at the fifth lumbar interspace. A review of these films revealed a narrowed fifth lumbar disc in 3 (33.3%). A posterior protrusion of the

Diagnosis—disc protrusion	10.4	11.1
Other diagnoses	3.9	3.9

fourth lumbar disc was revealed at operation in 2 cases. Both of these showed narrowed fifth lumbar intervertebral disc on the roentgenograms.

Of the 44 cases, 6 (13.7%) revealed posterior displacement of the fifth lumbar vertebra. Of the 6 cases with posterior displacement, 3 (50%) were associated with narrowed disc. No case of anterior displacement of the fifth lumbar vertebra was noted in this series.

DISCUSSION

Several of the roentgenographic and clinical findings seem worthy of brief discussion. The relationship which has been observed between the fourth and fifth lumbar disc measurements indicates the vulnerability of the lumbosacral articulation to mechanical strain, a point which has been emphasized by numerous observers. Any change in the usual anatomic structure of the lumbosacral joint, such as narrowed fifth lumbar disc, especially posteriorly, and anterior or posterior displacement of the lower lumbar vertebrae would in all likelihood place additional burden on a point of mechanical weakness and might produce pain in the lower back with or without leg radiation. Whether or not such complaints develop would depend on the ability of the as-

associated muscles and ligaments to compensate for the exaggerated mechanical strain.

It would appear that posterior displacement of the fifth lumbar vertebra is not uncommon and that it is not usually due solely to a difference in diameters of the fifth lumbar and first sacral segments. The exact cause of such displacement is conjectural and although it is assumed that anomalies of the lumbosacral facets are the basic predisposing factors, the roentgenograms offer no satisfactory evidence for this hypothesis.

Anterior displacement of the fifth lumbar vertebra occurs with half the frequency of posterior displacement and is almost always associated with a defect in the neural arch. In 44 per cent of cases there is compensatory tipping of the anterior edge of the sacrum.

Comparison of the anteroposterior diameters of the fifth lumbar and first sacral segments in attempting to explain the appearance of posterior fifth lumbar displacement on the roentgenogram, reveals that the fifth lumbar diameter in the entire group is greater than the first sacral in approximately 50 per cent. Where there is posterior fifth lumbar displacement, however, the fifth lumbar diameter is greater in about 90 per cent and where there is anterior fifth lumbar displacement it is greater in only about 25 per cent. Since it is known that anterior tipping of the sacrum is present very often in cases of anterior displacement and this might account for greater anteroposterior sacral diameter in these cases it would seem reasonable to consider, in cases of posterior displacement, the possibility of secondary atrophy of the anterior edge of the sacrum which would account for the lessened anteroposterior sacral diameter in this group.

The similarity between the clinical findings in the groups with and without narrow fifth lumbar disc and lower lumbar displacement is most striking. Since the incidence of back pain, leg pain, altered reflexes and limited straight leg raising is the same in the two groups, it would appear that in most cases narrow disc and lower lumbar displacement are not in themselves the cause of symptoms. This is reinforced by the similarity of incidence of narrow disc and lower lumbar displacement in cases with back pain alone, with

back and associated leg complaints, and in cases presenting neither of these symptoms. Only in the case of fifth lumbar displacement is there a different incidence in the groups with and without symptoms.

It is remarkable that the incidence of back and leg pain was the same in the two groups in spite of the fact that there was a much higher percentage of cases with lumbosacral arthritis in the patients with narrow disc and displacement. It might be deduced from this what has often been suspected namely that localized changes noted on the roentgenograms are not necessarily the cause of the patient's complaints. The greater frequency of arthritic change in the one group, however, would tend to confirm the belief that narrow disc and lower lumbar displacement cause increased lumbosacral strain and that such patients are more likely to develop decompensation of muscular and ligamentous structures as the result of acute or chronic trauma than are patients without these anatomic variations.

From the study of cases in which a diagnosis of ruptured nucleus pulposus or posterior disc protrusion was made it is apparent that the incidence of narrow fifth lumbar disc is no greater in this group than in other patients. Such an x ray finding cannot, therefore, be used as clinical evidence of disc protrusion.

From the roentgenographic and clinical data which have been accumulated it would seem that narrow fifth lumbar disc and lower lumbar displacement occur with similar frequency in patients with or without symptoms, that there is no characteristic clinical syndrome which they present and that they are not in themselves the cause of backache and leg pain. However, like other lumbosacral anomalies, they may further weaken the lumbosacral articulation and make it even more susceptible to injury.

This study has thrown no light on the etiology of these lower lumbar anomalies. Undoubtedly some are due to congenital defects, some to developmental changes, and others to the effect of acute and chronic trauma, but unless followed by muscular or ligamentous decompensation they are not necessarily productive of symptoms and are of no significant clinical importance.

SUMMARY

1 In a series of 500 roentgenograms focused over the lumbosacral joint, narrowed fifth lumbar disc was noted in 26.4 per cent, posterior displacement of the fifth lumbar vertebra was present in 10.2 per cent, anterior displacement of the fifth lumbar was present in 5.0 per cent, and there was displacement of the fourth lumbar vertebra in 3.0 per cent.

2 The incidence of back and leg pain in the 181 cases in which these changes were noted was not significantly greater than the incidence of these complaints in the other 319 cases.

3 When the two groups were studied clinically they showed a strikingly similar incidence of alteration in leg reflexes, limitation of straight leg raising and body tilt on forward bending.

4 The clinical diagnoses in the two groups were almost identical. There was however a considerably higher incidence of lumbosacral arthritis in the patients with narrow disc or lower lumbar displacement.

5 A study of the groups of patients with back pain alone with associated leg pain and with neither of these complaints revealed no significant difference in the incidence of narrowed fifth lumbar disc but there was a smaller incidence of lower lumbar displacement in the symptom free group.

6 Posterior displacement of the fifth lumbar vertebra is apparently a definite entity and is not due entirely to difference in anteroposterior diameters of the fifth lumbar vertebra and the sacrum although in about 20 per cent this is apparently the reason for the appearance on the roentgenogram. It is possible that in cases of posterior displacement there is secondary atrophy of the anterior edge of the sacrum which decreases the anteroposterior diameter of the first sacral segment.

7 Anterior displacement of the fifth lumbar vertebra is usually associated with a defect in the interarticular portion of this vertebra and in at least 40 per cent of the cases there is anterior tipping of the sacrum which increases the anteroposterior diameter of the first sacral segment.

8 In cases of herniated nucleus pulposus or posterior disc protrusion, the incidence of nar-

rowed fifth lumbar disc or lower lumbar displacement is not significantly greater than in the remainder of the series. Narrow disc on the roentgenogram cannot be considered clinical evidence of posterior disc protrusion.

9 Narrowed fifth lumbar disc and displacement of the lower lumbar vertebrae are clinically significant only in that these conditions place additional strain on an already mechanically vulnerable lumbosacral joint.

10 The weight of evidence seems to indicate that in most instances narrow fifth lumbar disc and lower lumbar displacement are in themselves not the cause of low back and sciatic pain. As is true in the case of transitional vertebrae and other lumbosacral anomalies the presence or absence of back or leg pain depends almost entirely upon the integrity of the surrounding muscular and ligamentous structures. So long as these structures are intact the patient may be symptom free. When they are no longer able to compensate for the abnormal mechanical strain pain may occur because of tension on muscle and ligamentous attachments, degenerative arthritic changes in the articular facets or actual pressure on the spinal nerves at some point in the region of the deranged lumbosacral articulation.

A CORRELATION OF NEUROLOGIC, ORTHOPEDIC, AND ROENTGENOGRAPHIC FINDINGS IN DISPLACED INTERVERTEBRAL DISCS

FRANCIS C GRANT, M.D., F.A.C.S., GEORGE AUSTIN M.D.,
ZACHARY FRIEDENBERG M.D. and ALTON HANSEN M.D. Philadelphia, Pennsylvania

ALTHOUGH the number of operations for displaced intervertebral disc has been steadily increasing comparatively few surgeons have published thorough reviews of their postoperative results. There remains considerable difference of opinion as to the precise indications for operation, the most favorable type of operation and whether or not a primary or secondary fusion should be attempted. Most reports have been limited to the problem of subjective improvement of back and sciatic pain and the objective neurologic changes following operation. Some authors have also attempted to correlate the effect of trauma and occupation with the etiology and degree of postoperative improvement (4, 8). Occasional papers have considered the result from an orthopedic or radiologic viewpoint (2, 3).

The purpose of this paper is to present a group of postoperative disc patients who have been critically studied neurologically and orthopedically. The results of these examinations were then integrated with the roentgen findings. In this way we hoped to determine any relationship that might exist between the preoperative and postoperative roentgenograms, the operative findings, and the eventual operative result.

For the purpose of this review a group of 95 postoperative intervertebral disc patients was collected from the Neurosurgical Service of the Hospital of the University of Pennsylvania. This series consisted only of patients operated upon for displaced lumbar intervertebral discs.

The follow up study consisted of a careful physical examination by members of the orthopedic and neurosurgical staffs. This was

followed by anteroposterior and lateral roentgenograms of the lumbar spine and pelvis. Neurologically the patients were examined for sensory motor and reflex changes. The lower limbs were checked for signs of atrophy or weakness and for the presence of pain on straight leg raising. Orthopedically, the patients were examined for any scoliosis, restricted mobility, paravertebral spasm or pelvic tilt. All patients were questioned as to the presence of any residual back pain or sciatic pain. Finally the patients were asked concerning their personal opinion of the operation. Each patient was asked if he was fully satisfied with the results of the operation and the results recorded as 'yes', 'no' or 'questionably satisfied'. The preoperative and postoperative findings were carefully compared and the preoperative and postoperative roentgenograms reviewed by a member of the radiology staff. An attempt was made to correlate the x ray findings with the postoperative physical findings in each case. A special study was made of those patients who were definitely not or only questionably satisfied.

The patients were divided into two main groups of laborers and non laborers, since it was felt that this difference in occupation might have a bearing on the etiology and the result. Also the possibility of trauma was listed in each case. The follow up period varied from less than 1 year to more than 5 years. The patients were divided into four groups as follows: less than 1 year (16 patients), 1 to 3 years (30 patients), 3 to 5 years (32 patients), and over 5 years (17 patients). Postoperative findings at operation were likewise divided into subgroups. Discs were listed as ruptured, protruded or hidden. In the remaining cases findings of hypertrophied ligamentum flavum or negative exploration were listed as such.

Dr. Austin is a Francis Clark Fellow in Neurosurgery.
From the Departments of Neurosurgery, Orthopedic Surgery
and Radiology of the Hospital of the University of Pennsylvania,
Philadelphia.

The type of operation seemed an important factor. Accordingly the operations were divided into three groups laminectomy hemilaminectomy and interlaminar dissection.

Indications for operation have varied somewhat over the years since this subject first came into prominence. During the past 4 years however we have become more conservative and have felt that the results were more gratifying from both the patient's and our own point of view. We first use conservative therapy in the form of rest and board mattress. Buck's extension for 10 to 14 days follows, and the patient is sent home with a brace or supportive belt. There is a decided advantage if the patient has had several recurrent bouts of severe pain before operation is eventually decided upon. If operation is performed when the patient has little or no back or leg pain the distress resulting from the operative incision may well make him feel that his condition has not been improved by surgery. But if his pain, particularly his leg pain, has been acute and is promptly relieved by removal of the disc, he is quite willing to put up with the postoperative back pain. He feels that he has been definitely improved by surgery. His attitude with regard to the final operative result is optimistic, a very important factor in obtaining satisfactory relief. Due to this preoperative conservatism we believe that we have increased both our proportion of ruptured discs found at operation and the percentage of satisfied patients. At present whenever possible the routine disc operation consists of an interlaminar dissection. Postoperatively weight bearing is permitted on the fifth to seventh day provided the patient has a light supportive belt. This we advise wearing for the first 6 weeks to 3 months. It is then to be discarded gradually as the patient increases his activities.

ETIOLOGY

The etiology of the displaced nucleus pulposus has remained an interesting question. The preponderance of male sufferers and the percentage of patients with a history of injury suggest a traumatic origin.

Of the 71 males and 24 females comprising the group studied 56 per cent claimed a traumatic onset.

It is of interest to note that almost as many non-laborers traced their disability to a traumatic incident as laborers. Half of the laborers remembered no one precipitating event.

The operative findings revealed that in the nontraumatic group 21 per cent showed indefinite findings such as hidden disc hypertrophied ligamentum flavum or no findings at all compared to only 13 per cent showing such indefinite findings in the traumatic group.

The majority of the patients were in their third and fourth decades the youngest being 19 and the oldest 63. Patients complained of back pain preoperatively for an average period of 5 years and sciatic pain for an average period of 2 1/4 years.

DIAGNOSIS

While the determination of the presence or absence of a ruptured disc depends, for the most part, on physical and neurologic findings other diagnostic aids are frequently used. In order to ascertain the reliability of some of these aids a study was made of the spinal fluid protein level conventional x rays, and myelography.

In 54 patients a spinal fluid protein was determined preoperatively. Forty-eight per cent of the readings were below 50.0 milligrams per cent while 43 per cent were between 50.0 and 100 milligrams per cent. In 9 per cent there were values over 100. These results indicate the doubtful value of the spinal protein in establishing a diagnosis.

The conventional roentgen examination consisted of an anteroposterior projection of the pelvis and lumbar spine and a lateral projection of the lumbar and lumbosacral spine. This type of examination was made in 68 patients preoperatively. In such conventional films preoperative roentgen changes were found in approximately one half of these patients. We do not believe that there is any absolute correlation between such findings and the presence of a displaced intervertebral disc or hypertrophied ligamentum flavum since an equal number of patients in this age group who do not have such disease will show similar roentgen changes. However appreciable narrowing of an intervertebral space indicates loss

Fig. 1. Relationship of postoperative time interval to back and sciatic pain.

of substance of the disc either by degeneration and absorption or by extrusion. When this is found in a patient with the usual clinical syndrome, we feel that it should be considered as corroborative evidence.

The changes seen in conventional preoperative roentgen examinations in 68 patients are reviewed in the light of operative findings.

Air myelographic studies were made in 15 patients of the series. Opaque myelographic studies were made in 61 patients of the series in 39 pantopaque was used and in 22, lipiodol. At the conclusion of the examination an attempt was made to remove the oil under fluoroscopic guidance in 45 of the 61 patients so examined.

The correlation of air myelograms with operative findings in 15 patients indicates that when a filling defect in the air column was found, surgical exploration was positive. The absence of a defect in an air myelogram, however, could not be considered as conclusive evidence that a lesion was not present.

From correlation of oil myelograms with operative findings in 61 patients it is evident, as others have also shown, that a high degree of accuracy is obtained in oil myelography. In this series a differential diagnosis was not

made between hidden disc, protruded disc, ruptured disc, and hypertrophied ligamentum flavum. The oil myelograms showed defects which appeared similar in these four conditions.

RESULTS

As previously indicated, the 95 patients seen postoperatively were divided into four groups for evaluation. The follow up periods ranged from less than 1 to over 5 years. When the patient was asked to evaluate his own result and whether or not he was fully satisfied and would again elect operation for his original complaints, knowing in advance what relief he could anticipate, 83 or 87 per cent of the patients replied in the affirmative. Seven per cent claimed they were dissatisfied, and 5 patients (5 per cent) could not decide. All of the discs operated upon in this series were between the fourth and fifth lumbar or the fifth lumbar and first sacral.

More detailed inquiries showed that there were 38 patients (40 per cent) who had residual or recurrent pain. This pain was not sufficiently incapacitating to invalidate the operation in the opinion of the patient. Complaints varied from occasional mild backache in 18 patients or sciatic pain in 4 to those with both

Fig. 2. A comparison of percentage of satisfied patients in various postoperative periods.

low back and sciatic pain present in 16. The largest number of these patients dated the onset of their pain to the operative period. A few claimed a recurrent type of pain originating 1 to 5 years postoperatively.

An analysis of the type of pain in the different follow up groups showed that a large number of low back complaints occurred in the patients most recently operated upon (Fig. 1). Complaints of low back pain associated with sciatic pain remain at a relatively constant level in each group.

Many diverse complaints of a mild nature were noted. Foremost among these was the presence of annoying muscular cramps in the hamstring and calf muscles on the side of the previous sciatica. Other patients noted low thresholds of back fatigue and subjective by paresthesias while a foot drop persisted in 1 patient.

An effort was made to determine which operative procedures gave the best results. Surprisingly enough there was no clear cut statistically significant choice between laminectomies, hemilaminectomies or interlaminar dissections.

Operative findings sharply influence results. Thirty nine out of 58 or 70 per cent of the patients with ruptured discs followed over 1 year were pain free. Four patients (44 per cent) with protruded discs were pain free as were 3 patients (50 per cent) of those with

hidden discs. Conversely there were only 6 patients (9 per cent) not satisfied when operative findings had revealed a definite rupture of the disc. Three patients (27 per cent) of those with protrusions were not satisfied, as were 2 patients (22 per cent) of those with hidden discs and 1 patient (50 per cent) of those with no findings at all. All of the 5 patients with hypertrophied ligamentum flavum were satisfied.

Although the presence of mild episodes of postoperative back pain was common in those patients with ruptured discs there was a low incidence of residual or recurrent sciatic pain. This finding contrasted with a higher incidence of residual or recurrent back pain and sciatic pain in those patients who at operation presented hidden or protruded discs. The possibility of a recurring disc may explain such a return of the original complaint in the protruded and hidden group.

From our studies it appears that absent or diminished tendo achillis reflexes do not often return postoperatively. In 74 instances this reflex was lost or diminished postoperatively on the involved side, and in 5 instances it was lost on the opposite side.

Fifteen among 48 (31 per cent) laborers did not return to their former occupations. They decided that they could not continue in their present work and chose lighter work. Some changed because they did not wish to abuse what they regarded as a weakened back while others changed after a trial at their old job which resulted in pain on doing certain types of heavy work. It is probably true that even a larger percentage than indicated modified their daily work although keeping the same job. Only 4 (9 per cent) out of the 47 non-laborers felt it necessary to seek other jobs. Five years postoperatively 4 patients (23 per cent) out of 17 still wore supports in the form of canvas belts or braces. All of these patients had complaints.

An analysis of the dissatisfied or questionably satisfied patients was undertaken (Fig. 2). One patient had expectations of recovering from a marked foot drop but no improvement in function followed the removal of the ruptured nucleus pulposus. This correlates with the failure of the achillis reflex to return.

Fig 3 Preoperative and postoperative films showing marked narrowing and early bridging

Two patients in whom hidden discs were removed complained of mild residual back pain and sciatic pain. The examination of the back was entirely negative in 1 while some restriction of motion was present in the other. Roentgenograms gave no clues to the causes of these complaints.

Three patients of the dissatisfied or questionably satisfied group had a recurrence of severe sciatic scoliosis spasm of the erector spinae muscles, and limitation of motion together with positive straight leg raising tests. This group might show a recurrence of the original pathology. The remaining patients complained of back pain with little explanation afforded for their complaints by physical examination. One of these patients operated upon 6 years ago with x ray evidence of narrowing of the interspace is relieved by a brace.

Postoperative roentgen studies. A study of the changes seen on the conventional roentgenograms made preoperatively and postoperatively and of the clinical status of the patients reveals that there is no significant relationship between increased narrowing of an intervertebral space and the clinical result. Increased arthritic change is seen in almost exactly the same proportion in the three classified groups of clinical results and consequently we feel that no significant relationship exists. Fusion or dense bony bridging between the vertebral

bodies above and below the site of the herniated discs is seen in only that group classified as clinically well. It might be presumed that this constitutes a favorable change. It occurred however, in only 6 of 39 or 15 per cent of the group.

A significant quantity of residual opaque oil was found in 10 of 36 clinically well patients in 1 of 17 clinically improved patients and in 3 of 8 clinically unimproved patients.

DISCUSSION

Results of other postoperative disc series vary from 24 per cent to 80 per cent cured (4, 5, 7). The present figure of 60 per cent cure compares favorably with these and emphasizes the difference between a straight neurosurgical clinic series and the cross sectional series of Aitken and Bradford. Their cases were reviewed from the files of a large insurance company and reveal a cross section of operative work done by general surgeons, orthopedic surgeons and neurosurgeons in various clinics throughout the country. They describe their results as excellent (13 per cent), good (17 per cent) and fair (25 per cent). The remaining 45 per cent were graded as 'poor' and 'bad' results. An excellent result they describe as 'no pain and able to return to any type of work.' This appears to be the only result comparable with 'cure' in other disc series.

Fig. 4. Normal preperitoneal films.

Fig. 5. Postoperative films of the same patient show, in the preceding figure show
 four narrow lines and early fusion.

The results of diagnosis by myelography show the increasing value of this procedure. Begg and Falconer reviewed the myelograms in a series of 86 patients with a disc found at operation. Eighty-eight per cent of these patients showed a positive myelogram for a disc preoperatively while 12 per cent showed

3 at the third lumbar interspace. They recommend exp centrally displaced discs bilaterally complete removal of all rupture material and to the level of the disc.

Fig 6 Preoperative and postoperative films showing narrowing and beginning bony fusion.

15 secondary fusions performed in their series and 9 of these or 60 per cent were able to return to some form of work. Love and Walsh believe that cases with frank spondylolisthesis with ruptured disc at the fifth lumbar—first sacral level usually require a fusion. However, they do not feel that narrowing of an interspace or the presence of spina bifida occulta is an indication for need of fusion. Love, in a recent review of 1,271 postoperative disc patients, questions whether or not fusion of the lumbosacral region causes more stress to be applied at the interspace just above the upper end of the graft with resultant protrusion. In this series he also shows that there is a marked rate of recurrence from less than $\frac{1}{2}$ per cent at the end of 2 years to slightly more than 5 per cent after 5 years postoperatively.

In a group of 843 patients operated on for ruptured disc by the late Walter Dandy, Lenhard was able to examine 147 in a postoperative follow up. Of these, 23.8 per cent were able to perform their normal activities without complaint. Three types of operation had been employed in this series. Prior to January 1942, to June 1943, curettage or removal of the entire disc was done. After June 1943, multiple discs were recognized and removed entirely. Practically all were done by an interlaminar approach. Analysis of the results showed that there was no relation between the

type of operative removal and the degree of cure. He likewise concluded that there is no relationship between a narrowed interspace and the faulty disc, the disc being found either at the level of the narrowed space or at the space above or below. No fusions were done in this series and no myelograms were deemed necessary since 90 per cent were at the fourth or fifth lumbar interspace. Lenhard feels that some of the patients with residual complaints due to tight muscles or faulty body mechanics could be helped by fusion.

The question of fusion has been closely analyzed by Barr in a series of 234 cases in which patients were operated on for ruptured disc. Of these, 102 had fusion and 132 had been operated upon without fusion. In reply to a questionnaire, the same percentage of each group (10 per cent) complained of severe back pain. Likewise, the same percentage in each group (63 per cent) stated that they were able to do a full day's work. However, there were 60 per cent of the fused group with no back pain and 45 per cent in the non-fusion group without back pain. Likewise, there were 25 per cent in the fused group that complained of leg pain compared to 46 per cent in the non-fused group with leg pain. He concludes that the trend is toward spinal fusion at the time of laminectomy in an increasing number of cases.

Fig. 4. Normal preoperative films.

Fig. 5. Postoperative films of the same patient show. In the preceding figure showing narrowing and early fusion.

The results of diagnosis by myelography show the increasing value of this procedure. Begg and Falconer reviewed the myelograms in a series of 86 patients with a disc found at operation. Eighty-eight per cent of these patients showed a positive myelogram for a disc preoperatively while 12 per cent showed a normal myelogram although disc was found at operation. Approximately 66% per cent of their cases showed a laterally displaced disc while 33% per cent were centrally located discs. The discs were almost equally distributed between the fourth and fifth lumbar interspace although 14 were multiple including

3 at the third lumbar interspace. They recommend exploring centrally displaced discs bilaterally to be sure of complete removal of all ruptured disc material and to avoid a recurrence. Love and Walsh are of the opinion that clinical diagnosis is just as accurate as myelography although they employ air almost routinely preoperatively. There are no definite conclusions on the subject of primary or secondary fusions following disc operations. Aitken and Bradford report on 39 primary fusions performed in their series. Of these 39 cases 19 or 50 per cent were able to return to some form of work. There were also

Fig 6 Preoperative and postoperative films showing narrowing and beginning bony fusion.

15 secondary fusions performed in their series and 9 of these or 60 per cent were able to return to some form of work. Love and Walsh believe that cases with frank spondylolisthesis with ruptured disc at the fifth lumbar—first sacral level usually require a fusion. However, they do not feel that narrowing of an interspace or the presence of spina bifida occulta is an indication for need of fusion. Love in a recent review of 1,271 postoperative disc patients questions whether or not fusion of the lumbosacral region causes more stress to be applied at the interspace just above the upper end of the graft with resultant protrusion. In this series he also shows that there is a marked rate of recurrence from less than $\frac{1}{2}$ per cent at the end of 2 years to slightly more than 5 per cent after 5 years postoperatively.

In a group of 843 patients operated on for ruptured disc by the late Walter Dandy, Lenhard was able to examine 147 in a postoperative follow up. Of these 23.8 per cent were able to perform their normal activities without complaint. Three types of operation had been employed in this series. Prior to January 1942 to June 1943, curettage or removal of the entire disc was done. After June 1943, multiple discs were recognized and removed entirely. Practically all were done by an interlaminar approach. Analysis of the results showed that there was no relation between the

type of operative removal and the degree of cure. He likewise concluded that there is no relationship between a narrowed interspace and the faulty disc, the disc being found either at the level of the narrowed space or at the space above or below. No fusions were done in this series and no myelograms were deemed necessary since 90 per cent were at the fourth or fifth lumbar interspace. Lenhard feels that some of the patients with residual complaints due to tight muscles or faulty body mechanics could be helped by fusion.

The question of fusion has been closely analyzed by Barr in a series of 234 cases in which patients were operated on for ruptured disc. Of these 102 had fusion and 132 had been operated upon without fusion. In reply to a questionnaire the same percentage of each group (10 per cent) complained of severe back pain. Likewise the same percentage in each group (63 per cent) stated that they were able to do a full day's work. However, there were 60 per cent of the fused group with no back pain and 45 per cent in the non fusion group without back pain. Likewise there were 25 per cent in the fused group that complained of leg pain compared to 46 per cent in the non fused group with leg pain. He concludes that the trend is toward spinal fusion at the time of laminectomy in an increasing number of cases.

SUMMARY

1. A group of 95 postoperative disc patients was studied by the neurosurgical, orthopedic and roentgenologic departments.

2. Sixty per cent of these patients were regarded as cured and were able to pursue a normal full day's work without any back or sciatic pain.

3. Eighty-seven per cent of these patients were fully satisfied with the results of the operation.

4. The factors of age, trauma or type of operation appear to have no relationship to the type of injury. Also the type of operation appeared to be unrelated to the result.

5. Air myelograms while helpful were not as accurate as desired in our experience. Oil myelography, preferably with pantopaque as the contrast medium, is the method of choice and should be routinely employed.

6. The end results will be more gratifying in proportion to the degree of displacement of the nucleus pulposus.

7. Lost or diminished achillis reflexes do not often return nor should a patient be allowed to believe paralysis will invariably recover following successful removal of the offending mass.

8. No relationship between increased narrowing of an intervertebral space and clinical result can be shown. Fusion of the vertebral bodies or dense bridging occurred in 6 patients, all of whom are in the group of clinically well. It could reasonably be postulated that more will develop this change as time goes on but further follow up studies will be necessary to substantiate or disprove this point.

9. It seems unlikely that the presence of a significant quantity of residual opaque oil in the caudal sac has any influence upon the clinical result.

10. The fundamental principle for good results is careful selection of patients with exclusion of those cases that fail to measure up to an exacting history and physical examination supported by myelography.

THE MANAGEMENT OF KNEE INJURIES INCURRED IN COLLEGE FOOTBALL

T B QUIGLEY M.D., Boston Massachusetts

OF the various insults to which the body of a football player is subjected injuries to the knee are among those fraught with the most serious consequences in terms of permanent disability. The middle aged business man with a trick knee dating from his high school or college football days is commonplace. A considerable proportion of these injuries can be prevented or minimized by proper protective measures and prompt adequate treatment.

The management of knee injuries has been a major concern of the medical staff of the Harvard Athletic Association since the appointment of the first team surgeon 38 years ago. The principles and policies which have evolved from this accumulated experience were first presented by Thorndike in 1938 (12). It is the purpose of the present report to review these principles and policies in the light of another decade of experience and to present the results of their application during the 1947 season to the varsity junior varsity and freshman squads. The 174 men in this group constituted about one third of the players regularly participating in contact sport during the fall season.

The management of any athletic injury is best considered from three points of view: prevention, immediate treatment and diagnosis and definitive therapy.

PREVENTION

No player is allowed to don a uniform until a history of past illnesses and injuries has been taken and a thorough general physical examination carried out by a physician on the staff of the Department of Hygiene of the University. All old injuries discovered during this procedure are immediately reported to the medical department of the Athletic Association.

Each knee is compared to the opposite knee with regard to quadriceps atrophy, lateral and medial collateral ligament laxity, cruciate ligament laxity, range of motion, and fluid (Fig 1). Almost invariably roentgenograms are taken. Marked muscular weakness or instability disqualify the player for contact sport. He is instructed in quadriceps and hamstring strengthening exercises and advised to return a year later for re-examination. Those players who present minor degrees of ligament laxity or a history of previous knee injury or operation are strapped with adhesive tape before every practice session and game throughout the season. The method of taping is known as the Duke Simpson strapping after the trainer who first devised it and provides in effect, an extra set of collateral and cruciate ligaments outside the skin. Properly applied (Fig 3) it produces great lateral and anterior posterior stability with no appreciable interference in flexion or extension. It does not significantly decrease the player's speed. A varsity player wearing full equipment and with a Duke Simpson strapping on both knees was able to run 100 yards from a standing start in 12.8 seconds. Daily taping during a 12 week season is likely to produce skin irritation. Tincture of benzoin compound has been used in the past as a protection before each application of tape, but during the 1947 season a formula devised by Dr. Martin Bellinger was found to be both cheaper and more effective.

Rosin G (powdered)
Ethyl alcohol

1 pound (453.6 gm.)
1 gallon (3785.4 c.c.)
1 "pinch" (0.15 gm.)

No candidate for the varsity junior varsity or freshman squads in 1947 was rejected because of weakness or instability of the knee. Of the 174 players comprising the squads 31 required daily protective taping. Of these 3 suffered a sprain of the medial collateral ligament during a game and 2 a recurrence of a

Fig. 1. Basic steps in examination of the knee. The subject is supine and completely relaxed. All steps are first carried out on the uninjured leg. A, Inspection and determination of extension. B, Determination of passive flexion. This follows a comparison of active flexion with the uninjured leg, and is not carried beyond the point of pain. C, Palpation for fluid. Pressure on the suprapatellar pouch drives small quantities of fluid down and. The right index finger is above about 1 cm. compresses the anterolateral aspect of the joint, producing fluid wave palpable by the thumb and left hand. D, Determination of muscle atrophy. The circumference of the thighs is measured at the same level. E, Determination of cruciate ligament laxity. The knee is flexed 90 degrees. The examiner's forearm presses firmly against the lower tibia while both hands grasp the leg just below the knee and manipulate it in the sagittal plane. F, Determination of collateral ligament laxity. One of the examiner's hands rests on the table and firmly grasps the femoral condyles. The other grasps the ankle and manipulates the extended knee in the coronal plane.

medial meniscus derangement. Occasionally in the past the medial or lateral components of the taping have been torn during a practice session or game. This has not occurred since the practice of folding the long collateral strips of tape on themselves as they cross the knee has been followed (Fig. 3D)

letic trauma, is the presence of a qualified doctor on the playing field. To leave to a trainer the decision as to whether an injured player shall continue to play or walk from the field, or be carried off is to gamble with permanent disability with the risk of being checked against the

QUIGLEY KNEE INJURIES INCURRED IN COLLEGE FOOTBALL

If after examination on the practice or playing field the doctor decides that further play is inadvisable the player is taken usually in a wheeled litter, to the field house where his clothes are removed and the knee carefully and gently surveyed for gross or major injury (Fig 1) Except in obviously minor injuries anteroposterior and lateral roentgenograms are taken. No exact diagnosis or prognosis is ventured at this time. If no major fracture is disclosed by x ray examination and no obvious gross injury is present a sponge rubber compression bandage is applied (Fig 2) and the entire leg is immersed for 30 minutes in ice water. Ordinarily this is accomplished within 10 minutes of the injury and is calculated to prevent hematoma formation at the site of the injury whether it be a contusion or a tendon or ligament sprain or a derangement or a combination injury. Sponge rubber known commercially as tan open-cell sponge is used and is compressed to half its thickness with elastic cotton bandage to produce a pressure of from 40 to 60 grams per square centimeter of skin. At the end of 30 minutes of chilling the wet compression bandage is replaced with a dry one. The player is fitted with crutches instructed in their use and taken either to his room or to the infirmary to remain in bed until the next morning with the leg supported on pillows above the level of the heart. The next afternoon the bandage is removed and again the knee is carefully surveyed. Any opinion given before this time is almost certain to be wrong. Twenty four hours are required for enough localization of pain and tenderness to permit diagnostic manipulation. If the compression bandage has been properly applied there will be little or no effusion. Occasionally there is slight edema of the leg distal to the bandage. Vascular complications including thrombophlebitis have not been encountered in any instance.

The injury is classified as a sprain contusion or meniscus injury and appropriate definitive treatment is instituted.

DEFINITIVE TREATMENT

Contusions. Contusions are the least common and least serious of knee injuries. Daily definitive treatment consists of heat in the

Fig. 2. Sponge rubber and elastic cotton compression bandage for immediate treatment of knee injuries.

form of whirlpool baths gentle stroking massage to stimulate lymphatic dissipation of hematoma and active exercise. Sponge rubber compression bandages are reapplied after each treatment over the anterior aspect of the joint until the possibility of effusion has passed.

When function is normal a padded fiber or plastic shield is taped over the site of the injury for a week or two lest a second blow at the same site produce a more disabling contusion. Nine contusions occurred during the season. Their severity and a detailed disability before the player could return to play are presented in Table I.

has been treated for 2 or 3 weeks and vigorous quadriceps exercise has been instituted. The usual management of meniscus injuries is well illustrated by the following case

N. R., a 22 year old 210 pound varsity lineman was struck by an opposing player on the lateral aspect of the left knee and complained of pain at the site of injury. He was removed from the game and the knee carefully surveyed. No abnormality was discovered and since full speed running and "cutting" were possible without pain he was returned to play. Several plays later without further injury the knee "gave way" and "something snapped" within

it. Again he was removed from the game and again examination including roentgenograms disclosed no abnormality. Cold and compression were applied and crutches were issued. Twenty four hours later there was slight effusion in the joint and fairly marked tenderness over the lateral collateral ligament from the joint line to the fibula. A diagnosis of sprain grade 2, of the lateral collateral ligament from massaging and definitive therapy consisting of wet heat, gentle massage and guided exercise instituted. Recovery was slow but a month later play was resumed with a protective strapping to the knee. On the first play after return to the line the knee was moderately twisted and locked in about 45 degrees of flexion with marked pain on its medial aspect. Once more

Fig. 2. Medial aspect of the knee joint after operation. The joint is held marked above. The medial collateral ligament has been torn from the patella and the medial meniscus from the femur. A suture has been inserted into the end of the anterior cruciate ligament.

could add compression were applied and crutches were used. Six days later there remained a rubbery block with lateral degrees of passive motion. Seven weeks over the antero-medial aspect of the joint line and moderate effusion it was now obvious that the original injury had been in all probability an example of the occasional tenderness of medial meniscus injuries. It manifested themselves by symptoms referable to the lateral aspect of the joint. Vigorous quadriceps exercises were instituted and 3 weeks later, a medial arthrotomy disclosed a bucket-handle laceration extending almost the whole length of the meniscus and displaced into the intercondylar notch. The lateral meniscus as far as could be seen was normal. The entire medial meniscus was removed. Quadriceps exercises were resumed immediately after operation and 2 weeks later crutches were discarded. Ten weeks after operation, protected by adhesive strapping, the player participated in spring practice except for scrimmages.

Only one other meniscus injury occurred among the squads under consideration during the 1937 season and this patient was not operated upon. It is unlikely that many meniscus injuries were overlooked since a close check is kept on the activities of all athletes throughout their college careers and any disability of significance would soon appear. The 174 players in the group participated in 102 practice sessions and games during the season, resulting in approximately 17,000 exposures to injury. Since there were 2 meniscus injuries during the season, a player might be said to have an expectancy of injury to one or another of his medial menisci of 1/17,000. This low incidence is attributed to prevention and early

treatment and is in contrast to the experience of Simon (9) of Louisiana who found it necessary to remove 35 menisci from 33 football players in 4 years at one university.

Dislocations. The rarest, but by far the most serious football injury to the knee is luxation of the tibia on the femur. Although as a rule roentgenograms should be made of any dislocation before reduction, the extreme rarity of fractures about the knee in football players and the grave danger to which the nerves and blood vessels are exposed in dislocations make immediate reduction on the field in the few moments before muscle spasm and pain occur the procedure of choice.

One such case occurred during the 1947 season, the first in over 16 years.

A 24-year-old 200-pound back was struck on the left knee and posterior aspect of the left knee by the flank of an opposing player. The foot remained behind the partially flexed knee was forced into the medial angle and the femur rotated internally approximately 90 degrees. The joint was dislocated laterally. Peripheral pulses and motion of the toes and knee were normal. Within 1 minute of the injury on the field, reduction was easily effected with almost no discomfort or difficulty. Roentgenograms disclosed no evidence of fracture. A sponge rubber compression bandage was applied and a temporary plaster of paris cylinder from the toes to the groin with the ankle at 90 degrees and the knee in 30 degrees of flexion. Four days later the joint was sprayed through a long curved medial incision (Fig. 3). The medial collateral ligament was found to be avulsed from its tibial insertion and lying within the joint. Its distal end in the intercondylar notch. Both cruciate ligaments were ruptured near their insertions. The medial meniscus was displaced to a vertical position in the intercondylar notch. The meniscus was removed, the torn ends of the cruciate ligaments approximated and the distal end of the avulsed lateral collateral ligament sutured in place. Fine interrupted cotton sutures were used throughout. Quadriceps exercises were begun immediately after operation and active motion on the eighth postoperative day. Crutches were discarded 2 weeks later. Three months after operation there was slight cruciate laxity 10 degrees of lateral laxity and a normal range of passive range of motion and the circumference of the left thigh was 1 inch less than the right. The player participated in winter track and spring baseball.

Although authoritative American and European opinion in general frowns upon operative intervention (2, 3, 10, 11, 14) prolonged immobilization would have accomplished little in this

TABLE III.—INCIDENCE OF ALL KNEE INJURIES WITH REGARD TO POSITION PLAYED

Position	Backs (4)	Ends (1)	Linebackers (3)
Average number of exposures per injury	245	200	208
Average disability in days per injury	3	12.8	7.2

case with the entire medial meniscus displaced into the intercondylar notch and the avulsed medial collateral ligament lying between the tibia and femur. Examination (Fig 1) under anesthesia followed by whatever surgical exposure is indicated (8) carries little risk establishes the diagnosis with precision and may well make a great deal of difference in subsequent disability. Fortunately no injury to the popliteal artery occurred in this case. When ischemia of the leg is apparent after reduction of a dislocated knee, immediate surgery is indicated. As soon as possible the popliteal space should be explored the damaged segment of artery inspected and if necessary excised or replaced with a vein graft a lumbar sympathectomy carried out and heparinization instituted. The experience of the two world wars with regard to wounds of the popliteal artery is disheartening (3 4 6 13) and only by such vigorous measures can gangrene be averted.

Statistical analysis with regard to position played It is of interest to study the incidence of knee injuries in general with reference to the position of the injured player on the team. The data are presented in Table III.

SUMMARY

1 The principles and policies of the medical department of the Harvard Athletic Association with regard to the management of knee injuries sustained in college football are presented.

2 Prevention, immediate treatment, and definitive therapy of contusions, sprains meniscus injuries, and dislocations are discussed.

3 The results of treatment of knee injuries occurring in the varsity junior varsity and freshman squads during the 1947 season are presented.

4 Two illustrative cases are presented.

THE EVALUATION OF SULFATHALIDINE AND STREPTOMYCIN AS ADJUNCTS IN PREPARING THE LARGE BOWEL FOR SURGERY

ROBERT J. ROWE, M.D., Dallas, Texas, EARLE H. SPAULDING Ph.D. DOROTHY S. MADAJEWSKI B.S. and HARRY E. BACON M.D. F.A.C.S. Philadelphia, Pennsylvania

THE value of antibacterial agents in preparing the bowel for surgery is recognized by the majority of surgeons and widely acclaimed by many as the greatest recent advancement in this field. A few surgeons have achieved excellent results without the use of these agents nevertheless it is our opinion that succinylsulfathiazole (sulfasuxidine) and phthalylsulfathiazole (sulfathalidine) have been influential factors in the relatively recent reduction in the mortality attendant upon surgery of the colon and rectum. The latter is exemplified by a recent series, performed by one of us (H. E. B.) of 146 consecutive bowel resections without a fatality.

Regardless of the merit of these drugs even the skeptic must admit that it would be ideal to have the bowel lumen aseptic at the time surgery is performed. Realizing that more potent antibacterial agents should be advantageous in further reducing the bacterial flora of the colon our interest was aroused by reports of various workers relative to the effect of oral streptomycin in experimental animals (3, 5, 11, 12). Since this substance was found to be effective against gram negative bacilli (4, 5, 10) was absorbed very poorly from the intestinal tract (12, 13) and, therefore relatively nontoxic systemically the thought immediately arose that here might be another useful adjunct in preparing the large bowel for surgery. It seemed likely that a combination of streptomycin and sulfathalidine might be even more efficacious chemoprophylactically. A clinical and bacteriological evaluation of

streptomycin as well as a combination of this substance with the sulfonamides, was therefore deemed advisable.

TECHNICAL RESUMÉ OF THE STUDY

At the time of conception of this study no reports were found in the literature relative to the effect of oral streptomycin on the bacterial flora of the large bowel in human beings. Due to the presence of such factors as partial obstruction secondary infection and lowered resistance which are found in the presence of carcinoma of the bowel it was felt that the use of patients who were actually being prepared for operation would enhance the value of the results. This made the problem more difficult, prolonged its termination and necessarily curtailed the number of patients studied. However all of the latter had carcinoma of the colon or rectum with one exception.

An attempt was made to control some of the variable factors which might influence the bacterial flora. After admission to the hospital, patients were fed a general diet until two preliminary stool specimens were obtained. After the second preliminary stool specimen was secured the drug was administered and all subsequent stool specimens were collected and numbered labeled according to the time of passage date hour of administration and type of drug. They were stored in a refrigerator immediately to prevent further bacterial growth. Each patient was placed on the same high calorie, high protein nonresidue diet supplemented by protein carbohydrate mixtures (2800 to 3000 calories daily). A fluid intake of 2500 to 3000 cubic centimeters daily was maintained. Only one dose of laxative was given to each patient 36 hours prior to operation. Patients requiring barium or cleansing enemas were eliminated. Individual studies usually ex-

Presented at the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, New York, September 20, 1947.

tended over a 6 or 7 day period but varied in a few cases from 2 to 12 days

Previously a brief comparative study of the relative effects of sulfathalidine and sulfasuxidine on the fecal coliform bacterial counts was made by three of the authors. The results were not sufficiently standardized to be included in the present study. Consequently sulfathalidine 0.1 gram per kilogram of body weight was administered daily in 6 doses to the first group of patients. The second group of patients received streptomycin, 2 grams daily dissolved in 12 cubic centimeters of water and administered in 2 cubic centimeter doses every 4 hours with a small amount of water. Several patients received a combination of streptomycin (2 gm daily) and sulfathalidine (0.1 gm per kgm of body weight daily).

BACTERIOLOGICAL STUDIES

A complete bacteriologic procedure for evaluating intestinal antiseptics must necessarily consider all types of bacteria found in the gastrointestinal tract. The entire flora of man is extremely varied and, to name only a few of the most important groups, consists of coliform bacilli (Escherichia coli, Aerobacter aerogenes and related organisms), enterococci, Clostridia, Bacteroides and the Shigella group of bacillary dysentery. Obviously the task of isolating and accurately identifying so many diverse species is an extremely complex one which the authors were not prepared to undertake. Instead two simpler methods were adopted namely (1) coliform count and (2) 'total count.' In the first named procedure a series of dilution tubes are cultured on eosin methylene blue agar, the coliform colonies counted, and this figure used to estimate the number of organisms in the specimen. The latter term 'total count,' denotes a method whereby an attempt is made to culture and count all of the important aerobes and anaerobes. Appropriate dilutions are added in duplicate to sets of veal infusion agar plates one incubated aerobically the other anaerobically. The word 'total' is used with qualification since the medium employed does not permit growth of certain bacterial genera, notably the lactobacilli.

Neutralization of drugs The relatively large amounts of sulfathalidine present in the specimens could be effectively neutralized by incorporating 5 milligrams per cent para-aminobenzoic acid in the water dilution tubes. Satisfactory inactivation of streptomycin was obtained with semicarbazide (8). The procedure was modified from that described by Rake and Donovick in that sodium acetate was employed in place of the potassium salt. From preliminary trials it was determined that effective inactivation occurred within 5 minutes and that the concentration of semicarbazide acetate carried over to culture plates was not itself inhibitory. Since high concentrations of streptomycin could be expected to be present in specimens it was necessary to determine how much could be inactivated under the test conditions. This figure was found to be 1320 micrograms per cubic centimeters which is the amount present in the first dilution tube from a 132 milligrams per gram specimen. The amount of streptomycin present in the feces of patients receiving 2 grams per day was determined by examining 80 random specimens and found to vary from 240 to 12,000 micrograms (12 mgm) per gram. Thus, the method appears to provide for more than tenfold the highest concentration actually observed.

Drug susceptibility As the study progressed the problem of reversion became more eminent and an explanation of the basis for this phenomenon was sought as well as proof that organisms actually were developing resistance to streptomycin. Consequently at the time of isolation selected strains were subcultured and stored in the refrigerator until needed. Susceptibility to streptomycin was estimated by the method of Bondi and associates. Sulfathalidine susceptibility was determined by the conventional broth tube dilution procedure.

Thirty-one isolations from 13 patients were studied in some detail for drug susceptibility. In each instance a coliform organism from a preliminary specimen was compared with one or more strains isolated during administration of drug. These bacteriological studies are being reported in detail in a separate publication.

Chart 1. Coliform counts after sulfathalidine administration, grams per kilogram of body weight daily. — Highest count in any patient. - - - lowest count in any patient. — average count of 6 patients.

Chart 2. Coliform counts after streptomycin administration, grams daily. — Highest count in any patient. - - - lowest count in any patient. — average count in 9 patients.

RESULTS

Sulfathalidine. Seven patients all with a adenocarcinoma of the rectum were given sulfathalidine. The results were uniform in 6 patients and are depicted in Chart 1. The preliminary counts varied from 10^6 to 10^8 and within 3 to 4 days dropped to less than 1250 organisms per gram of wet feces. The average drop occurred in 3½ days. Many of the plates at this time had no growth at all but since the use of lower dilutions was not considered practical values less than 1250 organisms per gram of wet feces were not determined. When the coliform flora has been decreased from 10^7 to 1000 it represents a reduction of 99.99 per cent.

One patient failed to respond in the usual manner. The explanation for this failure is not obvious since medication diet etc. were properly administered and the patient was very co-operative. Yet, the count remained high for 7 days and at the end of 10 days was still 12,500 organisms per gram of wet feces.

Streptomycin. When this study was conceived there was some question concerning the quantity of streptomycin that should be used. After conferring with Dr. J. Carlisle 2 grams was selected as the daily dosage. This was dissolved in 12 cubic centimeters of water and administered orally in 6 doses 2 cubic centimeters every 4 hours followed by a glass of water. Twelve patients received 2 grams of streptomycin daily. One patient had a re-

current carcinoma with a rectovesical fistula following sigmoidectomy performed at another hospital. At the end of 4 days his counts remained exceedingly high. In 2 other patients somewhat bizarre results were obtained. In 1 patient a susceptible *Aerobacter aerogenes* was isolated from the preliminary specimen and at the end of 62 hours a very resistant coliform organism (unidentified) was isolated from a stool with a 9,000,000 coliform count. In the other patient a susceptible coliform organism was isolated from the preliminary stool. At the end of 33 hours the coliform count in this patient was 260,000,000 and a resistant *Escherichia coli* was isolated. Operative intervention prevented further study and it was felt that definite conclusions should not be drawn in these instances.

Chart 2 diagrammatically represents the rather spectacular results which followed the oral administration of streptomycin in the 9 remaining patients. It was interesting to note that in 2 patients the count approached less than 1250 organisms within 12 hours. The longest time required for a drop to less than 1250 was 60 hours while the average time required was 48 hours.

Results were so excellent in the majority of these patients that it appeared that some of the streptomycin might have been wasted. Consequently a daily dose of 0.5 gram was employed in 6 patients. The results were in-

Chart 3. Coliform counts after 0.5 gram streptomycin daily. Reversion in 2 patients (K and J).

consistent (Chart 3) and in general the counts decreased slowly in this group. Reversion apparently occurred in patient K (Chart 3) and probably in patient J. In the latter patient sulfathalidine was started on the 8th day and the count was less than 1250 organisms within 24 hours. Reversion apparently occurred in patient F also. The elevation of the final count in patient D to 10 000 organisms per gram of wet feces may or may not be significant. From these observations it was obvious that 0.5 gram of streptomycin was not the optimum dosage.

Combined administration. Fourteen patients received combined therapy. It was necessary to eliminate 2 patients who received the correct dosage of sulfonamides but only 1 gram of streptomycin. Twelve patients received 2 grams of streptomycin and 0.1 gram of sulfathalidine per kilogram of body weight daily. A preliminary report of this work was given recently (1) and with the exception of minor changes our results and conclusions are the same at the present time. Results were exceptionally uniform during the first 3 days (similar to streptomycin above). In all patients except one the coliform counts were less than 1250 organisms per gram of wet feces within 48 hours. In the exceptional patient (patient B in Chart 5) the counts remained exceedingly high for 5 days and had these counts been included in the results which are shown in Chart 4 the average would have been completely distorted.

Chart 4. Coliform counts after combination of streptomycin 2 grams daily and sulfathalidine, 0.1 gram per kilogram of body weight, daily. — Highest count in any patient. — — — average count in 11 patients. . . . lowest count in any patient.

In most of these patients studies were carried on for several days and reversion of the counts was encountered in 3 patients. A graphic representation of this phenomenon may be seen in Chart 5. In each instance resistant organisms were isolated after the counts had returned to levels of 10^4 , 10^5 , and 10^6 .

Total fecal bacterial counts. The desirability of studying the entire fecal flora was recognized from the beginning of this problem. Because of the extensive work required for such studies however, it was decided to use coliform counts for the most part. Both coliform and total counts were performed on all specimens from 6 patients receiving a combination of sulfathalidine and streptomycin.

In 5 instances the coliform count dropped promptly and no reversion was noted the sixth patient showed a slow, gradual decrease for 5 days and reversion at 10 days. No significant change in total count was noticed in 2 instances and only a partial temporary drop in the other four. Streptomycin resistant organisms were isolated from the late specimens of all 6 patients.

DISCUSSION OF RESULTS

In the beginning of this study the authors believed that evaluation of streptomycin and sulfathalidine as chemoprophylactic agents would not be too complex but as our obser-

Chart 5. Reversion Coliform count following combination of sulfonamides and streptomycin, 3 of 8 patients

vations progressed the use of several patients was precluded by complicating factors such as incorrect diet inadequate medication and improper collection of specimens. In any case where there was some doubt as to the validity of the results the patient was eliminated. In complying with these requirements the total number of patients included in evaluating the results was reduced to 33.

Although this series is not large certain conclusions of clinical and bacteriologic value may be conjectured.

The results with sulfathalidine served merely to verify the work of Poth (6). There were only 7 patients in this group but the results were very consistent in 6. The bacterial counts dropped in every patient to a satisfactory level prior to surgery, although the average time required was 3½ days. No obvious reversion occurred in this group. One may conclude that sulfathalidine is a reliable agent for decreasing the coliform bacterial flora of the large bowel prior to surgery.

From our observations, large doses of streptomycin (2 gm. daily) appear to be excellent for reducing certain strains of coliform organisms in the large bowel and other investigators (14) have found it to be effective in reducing clostridial organisms. It was obvious from the results obtained after the administration of 0.5 gram of streptomycin daily that this dosage was not adequate. The reversion that occurred in patients K and J (Chart 3) was due to the appearance of a streptomycin resistant coliform organism. The frequent occurrence of

Chart 6. Average coliform count — — — Sulfathalidine 0.5 gram per kilogram of body weight daily — — — streptomycin 2 grams daily — — — even 4 of, same dose

this phenomenon would apparently preclude the use of such small doses of streptomycin.

Results in the group of patients who receive a combination of streptomycin and sulfathalidine were somewhat disappointing since it was our hope that sulfathalidine and streptomycin in combination would entirely prevent reversions due to the appearance of drug fast organisms. Such was not the case. However the combination of drugs was superior to either one alone in one important respect namely the rapidity with which the coliform count dropped (see Chart 6). If the study of these patients had been limited to 3 days the results would have been classified as excellent. Fortunately most of the studies were extended over longer periods of time and other important observations were made for example the frequency with which reversion in counts occurred. Although it is well known that drug resistant organisms often appear during treatment with streptomycin we had hoped that combined administration with sulfathalidine would prevent the occurrence of this phenomenon. Nevertheless 3 of the 12 patients had a reversion of their counts and pure cultures of streptomycin resistant organisms were isolated in each instance. One was apparently resistant to sulfathalidine but the others were not tested. In patient II contamination occurred during the operation with a resulting peritonitis, multiple intra abdominal abscesses and death. Without the aid of the antibiotics and sulfonamides therapy was hopeless. The re-

covery of streptomycin resistant organisms from the late specimens of the 6 patients in this group upon whom total counts were performed, adds further support to the theory, that prolonged administration of streptomycin is not desirable. It is unlikely that a combination of these drugs, at least in the doses used by us can significantly alter the total bacterial population for prolonged periods of time.

Analysis of the bacteriologic data suggests only one explanation for the reversion in coliform counts which were encountered, i.e. the appearance and multiplication of a drug resistant organism. On the other hand, reversion did not always accompany the appearance of a resistant coliform, provided the patient was receiving both streptomycin and sulfathalidine. The obvious explanation for such a discrepancy is that those bacteria resistant to streptomycin were, nevertheless, susceptible to the sulfonamide. Experimental evidence to support this view was obtained in several instances. Thus the development of resistant coliform organisms should occur less frequently in patients receiving a combination of the two drugs. Although our data show reversion occurring as frequently in the group receiving the combination as in the group with streptomycin alone this is possibly due to the limited number of cases involved.

The results obtained with the combination of drugs indicate that administration for 24 hours is sufficient to reduce the coliform population of the bowel by approximately 99.99 per cent. Apparently no harm is done by continuing the program for a total of 48 hours. Further prolongation, however, runs the risk of encouraging development of bacteria resistant to streptomycin and should be avoided.

Although we found that sulfathalidine required on the average $3\frac{1}{2}$ days to produce a base line drop in coliforms, Poth's figures in a large series of cases indicate that 5 to 7 days may be necessary for consistent results. Because he has obtained such excellent healing of intestinal anastomoses with this regimen (6), we hesitate to recommend a shorter period. Since combined administration appears to have merit we feel safe in proposing the use of sulfonamides for 5 days with the addition of streptomycin 48 hours prior to surgery.

It should be emphasized that the chemoprophylactic program recommended was not subjected to bacteriological study but rather is derived from our results. In the future it may be found that larger doses of streptomycin are advantageous.

In these preliminary experiments we have limited ourselves largely to the coliform count. *Escherichia coli* is only one of the many intestinal inhabitants. Recent studies by other investigators, as well as our own limited data obtained from "total counts," indicate that fecal coliform counts do not accurately reflect trends in total population. More accurate evaluation of the chemoprophylactic effectiveness of the sulfonamides and streptomycin must await results of more detailed studies.

SUMMARY

1. Certain properties of streptomycin indicated that it would be a valuable adjunct in preparing the large bowel for surgery. Therefore a comparative evaluation of sulfathalidine, streptomycin and combinations of the two was undertaken, patients with carcinoma of the rectum or colon being used as subjects.

2. The intestinal bacterial flora was studied by means of coliform and total bacterial counts. An explanation of reversion of these counts was sought through the study of drug susceptibilities of selected strains of organisms.

3. The average fecal coliform count decreased by 99.99 per cent in $3\frac{1}{2}$ days with 0.1 gram per kilogram of body weight daily of sulfathalidine in 2 days with 2 grams of streptomycin and in 24 hours with a combination of the two.

4. Reversion in count due to resistant organisms was not observed with the sulfonamide, but did occur with streptomycin especially in those patients who received (0.5 gm) daily. Combined use of the two drugs did not entirely prevent this phenomenon.

5. A coliform organism which became resistant to both drugs preoperatively was responsible postoperatively for a generalized peritonitis which proved fatal.

6. On the basis of our preliminary experiments the use of streptomycin alone cannot be recommended. However a program which includes sulfathalidine for 5 to 7 days and the addition of streptomycin 48 hours prior to sur-

gery is worthy of trial. With this program the benefit of the higher antibacterial activity of streptomycin is obtained and the risk of producing resistant organisms is thus minimized.

7. Bacteriological studies indicated that the coliform count fails to reflect accurately the total colonic bacterial population including important pathogens.

8. More conclusive evaluation of the effectiveness of these drugs on the fecal bacterial flora awaits the results of similar and more detailed investigation.

TUMORS OF THE VERTEBRAL COLUMN

J PUIG GURI M D., Iowa City Iowa

ABNORMALITIES in the density, structure, or general configuration of the vertebral bodies or neural arches may be produced either by tumors arising primarily in the vertebral column or surrounding structures or as a consequence of metastasis from neoplasms located in other parts of the body. Due to the proximity of some important organs and of the central nervous system to the vertebral column the prognosis as well as the treatment of these tumors is somewhat different from that for the same type of lesions located in the extremities. In order to obtain a better clinical understanding of these neoplasms, we studied all the patients with tumors of the vertebral column seen at the State University of Iowa Hospitals with good clinical and roentgenographical follow up.

It is not our aim to discuss all the aspects of this problem or to give a complete review of the literature but to describe in detail those vertebral tumors which due to their localization evolution response to treatment or end result, warrant consideration. Although this report is mainly concerned with the primary tumors of the vertebral column, tumors affecting the spine through contiguity or metastasis were also included. Only the primary tumors of the vertebral column which could be examined microscopically and the metastatic tumors to the spine with known primary lesion were included in this study.

HEMANGIOMA

Two patients with hemangioma of the vertebra were studied. One of these tumors was found at autopsy in the body of the eighth dorsal vertebra. It had never produced clinical symptoms.

The second patient was a 42 year old woman who sustained a fall 6 months prior to admission. Then she complained of numbness in both legs and right arm, and difficulty in walking. Neurological examination

showed the presence of compression of the spinal cord at the level of the lower cervical spine. The anteroposterior roentgenogram showed a honey-comb-appearing lesion involving the body and neural arches of the seventh cervical vertebra. The lateral roentgenogram showed a marked increase in size of the vertebral body bulging of the walls, and new bone formation (Figs 1a and 1b).

The patient was treated by means of roentgen therapy with temporary improvement of the symptoms. However the patient's condition became suddenly worse, and an almost complete paralysis on the right side of the body developed. A laminectomy was immediately performed and on removal of the lamina of the seventh cervical vertebra, the bone was found to be very vascular. No extradural soft tissue tumor was encountered. Microscopical studies confirmed the diagnosis of hemangioma. The patient recovered very quickly following the operation, and when last seen in this hospital, 13 months after operation the only residual symptom was a slight weakness of the right arm. The roentgenogram at that time showed the lesion to be unchanged.

While vertebral hemangiomas are frequently found at autopsy (10.7% in Schmorl statistics 11.93% in Topper statistics) the diagnosis is rarely made clinically. This may be due either to the lack of symptoms given by the vertebral hemangiomas or to the difficulty of its roentgenographic visualization. Connell and Hay, and Hammes have reported proved cases of hemangioma involving the neural arches in which repeated x ray examinations were completely negative.

The usual site of the vertebral hemangioma is in the dorsal and lumbar regions (Blackford, Kelly, Perman, Livingston, Ireland). Hemangioma of the cervical vertebrae is an extremely rare entity. Bucy and Capp in 1930 stated that there were no cases involving the cervical vertebrae. Heaney and Whitaker reported in 1933 the first case involving the axis but their diagnosis was based on the roentgenogram only and no histological examination was obtained. The first histologically proved case of hemangioma involving the cervical spine and producing compression of the spinal cord was reported by Geschickter and Keasbey. It involved the bodies of the fourth, fifth and sixth cervical vertebrae.

From the Department of Orthopedic Surgery, State University of Iowa, Iowa City.

Schlesinger and Ungar in 1939 described another histologically proved case, involving the seventh cervical and causing compression myelopathy. In 1941 Ghormley and Adson reported 39 cases of vertebral hemangioma of which only 1 was of cervical localization.

Holta in 1942 reported a new proved case involving the body of the fourth cervical that had produced a pathological fracture.

Due to the fact that many of the present day foreign periodicals are not available, a complete review of the literature was impossible. However investigation of most of the American and foreign publications since 1930 has failed to reveal any additional cases. Consequently our patient may be considered the sixth case of cervical hemangioma producing clinical symptoms to be reported in the literature and the fourth one of such localization proved by microscopical studies.

Regarding the treatment of this condition most authors agree that the best results can be obtained by means of roentgen therapy. Surgical intervention is advisable when there are persistent signs of cord compression but other wise is contraindicated because of the high mortality produced by the postoperative bleeding (1 of 5 patients operated upon according to Ferber and Lampe 21 1% mortality according to Schlesinger and Ungar).

The increase of the neurological signs following roentgen therapy in our patient justified surgical intervention.

GIANT CELL TUMOR

Since 1924 when Lewis reviewed 16 cases previously reported in the literature and added a new one, several authors have described this condition (Santos and Jenkinson and Hunter McFarlane and Linell Willard and Nicholson) making a total of 91 cases reported up to 1945 (Brock and Bogart).

In the files of this hospital 3 cases of giant cell tumor involving the spine were found. Both were in patients of the same age and the lesions were localized in the second and third sacral segments. Although according to Richards and Singleton giant cell tumors of the spine may be of the osteolytic or of the osteoblastic variety both our patients had a purely osteolytic lesion involving one sacral segment.

Both lesions appeared in patients belonging to the same age group and in the same location however the end results were completely different.

A 13 year old male was seen here 4 months following direct trauma over the sacrum. He complained of localized sacral pain present only when sitting. His general condition remained excellent throughout. On local physical examination a tender spot 3 inches below the posterosuperior iliac spine was found. On rectal examination a tumor situated in front of the sacrum was palpable. Roentgenographic studies demonstrated the presence of an osteolytic lesion that had entirely destroyed the third sacral segment (Fig 2a). No perosteal reaction was present. A biopsy was performed and during operation the destruction was found to have been so complete that a finger could be introduced through both walls of the sacrum. The frozen sections demonstrated a giant cell tumor and it was decided to suture without any further surgery.

The patient received 800 roentgens postoperatively. Serial roentgenograms taken every few months demonstrated disappearance of the osteolytic area and reconstruction of the second sacral segment (Fig 2b). There was no metastasis.

The patient was periodically checked for at least 3 years. Six years after biopsy, the patient was in excellent general condition and in active military duty.

The other patient, a 13 year old female had spontaneous onset of paresthesias in both legs without previous trauma. One week later bladder disturbances and weakness of the lowers were present. On admission (3 weeks after the onset of symptoms) her gait was unsteady and her legs very weak. Physical examination demonstrated the existence of anesthesia over the second, third, and fourth sacral dermatomes, loss of rectal tone and absent deep reflexes in the lowers. Spinal fluid and blood chemistry studies were negative. Complete destruction of the second sacral segment was observed in the roentgenograms.

A very vascular tumor growing around the sacral roots and completely destroying the second sacral segment was found at the operation. Due to the infiltrative character of the process, only a partial removal of the mass was possible. Following surgery 300 roentgens were given.

The patient progressively improved and a few weeks afterward she was able to walk, the rectal and bladder control being again normal.

Two months after operation, patient developed a sudden catch in the left side of her back. Most of the previous signs recurred, this time being more marked on the left lower extremity. Physical examination showed the presence of a fluctuant swelling about the size of an apple over the sacral region. Aspiration biopsy confirmed the recurrence of the giant cell tumor but no histological signs of malignancy were found. The roentgenograms showed

Fig 1 a and b, Hemangioma involving the seventh cervical vertebra c, Microscopic aspect, low power

advanced destruction of the sacrum and a pathological fracture through the wing of the sacrum was already present. Further roentgen therapy was administered. The patient died 16 months after the initial surgical intervention.

The end results obtained in these two giant cell tumors which were devoid of pathological signs of malignancy were striking. Although both patients were operated upon in the first one only a biopsy was performed. In the second case a partial removal was necessary due to presence of neurological signs of compression. Some authors state that biopsy (Brailsford Kolodny and Pfahler and Parry), curettage partial or total removal (Bower Clark and Davis) may stimulate further activity or facilitate the apparition of recurrences especially when they are combined with irradiation (Coley and Higinbotham). As in our second case patient was treated by means of partial removal plus x ray therapy it is possible that the treatment influenced the evolution of the tumor but it will be unfair to forget that the partial surgical removal was not an elective measure but determined by the intrinsic infiltrating characteristics of the tumor—characteristics that were not present in the first case.

On establishing the indications for the treatment of giant cell tumors of the spine we must

take into consideration their location. When they involve only the neural arches successful cures after complete removal have been reported (Vegh Milch). If the involvement of the vertebral body is only partial and in an area close to the pedicles, successful results can also be obtained by removal of the involved arches and curettage of the vertebral body (Duncan and Ferguson). When the tumor occupies most of a vertebral body the treatment of choice is roentgen therapy. Several cases have been described in the literature in which a complete reossification of the vertebral body took place following treatment as

Schlesinger and Ungar in 1939 described another histologically proved case, involving the seventh cervical and causing compression myelopathy. In 1941 Ghormley and Adson reported 39 cases of vertebral hemangioma, of which only 1 was of cervical localization.

Holts in 1942 reported a new proved case involving the body of the fourth cervical that had produced a pathological fracture.

Due to the fact that many of the present day foreign periodicals are not available, a complete review of the literature was impossible. However investigation of most of the American and foreign publications since 1930 has failed to reveal any additional cases. Consequently our patient may be considered the sixth case of cervical hemangioma producing clinical symptoms, to be reported in the literature and the fourth one of such localization proved by microscopical studies.

Regarding the treatment of this condition most authors agree that the best results can be obtained by means of roentgen therapy. Surgical intervention is advisable when there are persistent signs of cord compression but otherwise is contraindicated because of the high mortality produced by the postoperative bleeding (1 of 5 patients operated upon according to Ferber and Lampe; 11 1% mortality according to Schlesinger and Ungar).

The increase of the neurological signs following roentgen therapy in our patient, justified surgical intervention.

GIANT CELL TUMOR

Since 1924, when Lewis reviewed 16 cases previously reported in the literature and added a new one several authors have described this condition (Santos and Jenkinson and Hunter McFarlane and Linell Willard and Nicholson) making a total of 91 cases reported up to 1945 (Brock and Bogart).

In the files of this hospital 2 cases of giant cell tumor involving the spine were found. Both were in patients of the same age and the lesions were localized in the second and third sacral segments. Although according to Richards and Singleton giant cell tumors of the spine may be of the osteolytic or of the osteoblastic variety both our patients had a purely osteolytic lesion involving one sacral segment.

Both lesions appeared in patients belonging to the same age group and in the same location however the end results were completely different.

His general condition remained excellent throughout. On local physical examination a tender spot 2 inches below the posterosuperior iliac spine was found. On rectal examination a tumor situated in front of the sacrum was palpable. Roentgenographic studies demonstrated the presence of an osteolytic lesion that had entirely destroyed the third sacral segment (Fig. 2a). No periosteal reaction was present. A biopsy was performed and during operation the destruction was found to have been so complete that a finger could be introduced through both walls of the sacrum. The frozen sections demonstrated a giant cell tumor and it was decided to suture without any further surgery.

The patient received 800 roentgens postoperatively. Serial roentgenograms taken every few months demonstrated disappearance of the osteolytic area and reconstruction of the second sacral segment (Fig. 2b). There was no metastasis.

The patient was periodically checked for at least 3 years. Six years after biopsy, the patient was in excellent general condition and in active military duty.

The other patient a 13 year old female had spontaneous onset of paresthesias in both legs without previous trauma. One week later bladder disturbances and weakness of the lowers were present. On admission (3 weeks after the onset of symptoms) her gait was unsteady and her legs very weak. Physical examination demonstrated the existence of anesthesia over the second, third, and fourth sacral dermatomes, loss of rectal tone and absent deep reflexes in the lowers. Spinal fluid and blood chemistry studies were negative. Complete destruction of the second sacral segment was observed in the roentgenograms.

A very vascular tumor growing around the sacral roots and completely destroying the second sacral segment was found at the operation. Due to the infiltrative character of the process, only a partial removal of the mass was possible. Following surgery 1200 roentgens were given.

The patient progressively improved and a few weeks afterward she was able to walk, the rectal and bladder control being again normal.

Two months after operation patient developed a sudden catch in the left side of her back. Most of the previous signs recurred, this time being more marked on the left lower extremity. Physical examination showed the presence of a fluctuant swelling about the size of an apple, over the sacral region. Aspiration biopsy confirmed the recurrence of the giant cell tumor but no histological signs of malignancy were found. The roentgenograms showed

Fig 1 a and b, Hemangioma involving the seventh cervical vertebra c, Microscopic aspect, low power

advanced destruction of the sacrum and a pathological fracture through the wing of the sacrum was already present. Further roentgen therapy was administered. The patient died 16 months after the initial surgical intervention.

The end results obtained in these two giant cell tumors which were devoid of pathological signs of malignancy were striking. Although both patients were operated upon in the first one only a biopsy was performed. In the second case a partial removal was necessary due to presence of neurological signs of compression. Some authors state that biopsy (Brailsford Kolodny and Pfahler and Parry), curettage partial or total removal (Bower Clark and Davis) may stimulate further activity or facilitate the apparition of recurrences especially when they are combined with irradiation (Coley and Higinbotham). As in our second case patient was treated by means of partial removal plus x ray therapy it is possible that the treatment influenced the evolution of the tumor but it will be unfair to forget that the partial surgical removal was not an elective measure but determined by the intrinsic infiltrating characteristics of the tumor—characteristics that were not present in the first case.

On establishing the indications for the treatment of giant cell tumors of the spine we must

take into consideration their location. When they involve only the neural arches successful cures after complete removal have been reported (Vegh, Milch). If the involvement of the vertebral body is only partial and in an area close to the pedicles successful results can also be obtained by removal of the involved arches and curettage of the vertebral body (Duncan and Ferguson). When the tumor occupies most of a vertebral body the treatment of choice is roentgen therapy. Several cases have been described in the literature in which a complete reossification of the vertebral body took place following treatment, as

Fig. a, Destruction of the body of the third sacral segment 4 months after onset. b, Reconstruction of the third sacral segment following ray therapy. c, Microscopic aspect, high power.

sacrococcygeal region. However they may appear at any level of the spine and undergo malignant degeneration giving origin to tumoral neoformations.

The clinical signs of these tumors depend to a great extent on their location. The roentgenograms usually show an area of rarefaction without signs of new bone formation. In the advanced stages, a soft tissue shadow can also be observed.

The microscopical structure of the chondromas is by no means uniform. Regional variations can be observed even in the same tumor. Among our material there was a specimen (for which a clinical record was not available but that was included in this report because it allowed an excellent histological understanding of this condition) in which some regions appeared formed by solid rods of cells having an epithelial appearance (Fig 3b). In other regions the tumoral cells had a clearer protoplasm or presented a marked distended protoplasm full of mucinous material (physaliphorous cells of Virchow).

The process of vacuolation and mucin formation is more pronounced in other cases in

happened in our first case (Brock and Bogart, Brunswick Cotton).

Spontaneous cures may occur as described in a case reported by Murphy following pathological fracture.

CHORDOMA

According to Ehrenhaft notochordal tissue remnants are found during postmortem examinations in 2 per cent of the cases. They usually appear in those areas in which only a moderate amount of cartilaginous tissue surrounds the chorda, i.e., the base of the skull and

Fig 3 a Chordoma destroying the sacrum. Photograph obtained from a microscopic slide, enlarged 2 times. b, Microscopic aspect through the upper part of the tumor. High power. c, Microscopic aspect through the lower part of the tumor. High power.

which the cells adopt a syncytium like appearance. A great amount of mucin is present in the intercellular spaces (Fig 4b). Areas of necrosis are not infrequent.

These different histological aspects have been explained by Alezais and Peyron on basis of the different stages of evolution of the notochord. Steward described the presence of nuclear vacuolation and stated that it was more frequent in the cellular parts of the tumor being apparently absent in the areas with abundant mucin. Steward and Morin reported the existence in these tumors of spherical bodies formed by concentrically arranged groups of cells that they compared to 'nests of beakers'. Although the presence of such formations has been confirmed by Cappell we were unable to find them in our histological sections.

It is at present widely accepted that the best treatment of these tumors is their total resection (Mixer and Mixer Mabrey) because as a rule they are radioresistant. The evolution of the case corroborates this point of view.

A 54 year old male suffered a direct trauma over the sacrum 2 years before admission. This was followed by persistent pain which became progressively worse until he was unable to work and sleep

Fig 3a.

A few months later he developed some rectal trouble and a so called rectal abscess was incised. The patient was relieved for 3 months following which the sharp stabbing pain reappeared. Two weeks before admission the patient complained of radiating pain along the outer aspect of the leg and foot, with a sensation of numbness in the outer aspect of the thigh.

Fig. 4a.

The local physical examination showed marked spasm of the sacrospinalis muscle and a swollen and acutely tender area covered by edematous skin extending from the fourth lumbar vertebra down the entire left buttock. Rectal examination showed the presence of some tenderness over the sacrum and coccyx. The roentgenograms showed the distal portion of the sacrum to be markedly destroyed by an osteolytic process that involved both sacral wall (Fig. 4a).

The diagnosis of chondroma was made first by an aspiration biopsy. The surgical biopsy confirmed the diagnosis. Histological studies showed the presence of basophilic cells with large nuclei and finely vacu-

Fig. 5. Microscopic aspect of chondroma arising from the body of the sixth dorsal vertebra.

b

Fig. 4. a, Chondroma destroying the sacrum. b, Microscopic aspect, lower power.

lated protoplasm. The borders of the cells were indistinct and some of them appeared very distended. Many signet-ring forms were present. No mitosis was observed but there was considerable nuclear pleomorphism.

The tumor was considered to be too widespread to be surgically removed. Roentgen irradiation treatments were given. In spite of this treatment, the tumor continued to increase in size. Although the patient had temporary relief of his pain following each treatment, neurological signs of cauda equina

Fig. 6. Calcified chondroma arising from the posterior surface of the sacrum. Sacral contours outlined in white.

Fig 7. a and b, Fibrosarcoma involving the neural arches of several lumbar vertebrae. The upper portion of the tumor is calcified. c, Microscopic aspect of the tumor high power

compression and root involvement appeared. Locally, a hard mass of osseous consistency could be palpated in the buttock.

In order to relieve the pain it was necessary to perform a chordotomy. No metastasis could be observed after several roentgenographic examinations. The patient died 2 years after first admission.

CHONDROMA

Benign cartilaginous tumors arising from the neural arches have been frequently reported (Paulian and Bistriceano, Rix and Geschickter). Chondromas arising from the vertebral body itself are considered less frequent. The patient studied by us is of particular interest. The evolution of his cartilaginous tumor seemed to corroborate the statement made by Geschickter that the prognosis of chondromas is not dependent upon the histological picture but upon their localization.

A 45 year old female on admission complained of sharp pains of 9 months duration over her right chest, associated with the respiratory movements. The intensity of the pain had been progressively increasing.

On admission the physical examination was inconclusive. Roentgenograms of the dorsal spine, taken following induced pneumothorax, showed the

presence of a mass at the lateral side of the body of the sixth dorsal vertebra. A few days later a laminectomy was performed and a tumor the size of an egg arising from the body of the vertebra and projecting inside the pleural cavity was found. Anatomopathological studies showed the presence of a chondroma (Fig 5).

Following resection she was very well for about 1 year when the same type of symptoms but with greater intensity reappeared. Repeated roentgenograms showed the recurrence of the growth at the same level. At operation a mass the size of a golf ball was found in the same previous localization. A very careful complete removal of the tumor was performed and microscopical studies showed a typical chondroma without signs of malignancy. After operation, roentgen therapy was instituted.

Fig. A. Microscopic aspect of chondrosarcoma involving the eighth dorsal vertebra.

Following the operation she was completely free from pain for only a short while. A few weeks later she started to complain of pain over the abdomen. The gall bladder and the appendix were removed without the slightest relief. A body brace was then given.

She returned after 4 years complaining of weakness and numbness of the legs, inability to walk, and numbness in the abdominal wall. Physical examination showed a paraplegia with hyperactive deep reflexes and sensory loss from the level of the fourth dorsal dermatome down to the toes. A recurrence of the tumor was detected on the roentgenograms,

Fig. p. a. Multiple myeloma involving the dorsal spine.

with destruction and mild compression of the same vertebral body. New surgical intervention was performed and a huge chondroma compressing the cord was found. The tumor completely invaded the vertebra and the ribs. Only a sufficient amount to make the spinal canal as large as normal was removed. The aspect of the tumor was unchanged. In microscopic examination no signs of malignancy could be found.

Following operation the pain did not diminish and it was necessary, later on, to perform a chordotomy. The patient died 6½ years after first admission.

When these tumors are localized at the neural arches and grow posteriorly they may reach enormous sizes without producing serious complications as demonstrated by the case reported by Ljachovitzky in the cervical spine and by one of our cases arising from the sacrum and producing an enormous growth during an interval of several years.

A 61 year old male gave a history of fall on left hip 10 years prior to admission. Six years following the fall the patient noticed a lump over the left side of the sacral region. It was neither painful or tender but the patient noticed some back pain after a heavy day's work. The mass grew very slowly until 3 years before admission, at which time it began to grow more rapidly. Six months before admission there was some tenderness on palpation, the mass became swollen and began to produce a steady aching type of pain with short intervals of radiation down to the left leg. There was no loss of weight or appetite and the general condition of the patient remained excellent throughout.

On physical examination a hard, nodular growth measuring 15 by 10 by 7 centimeters fixed to the sacrum was found. It was slightly tender on palpation. On the roentgenograms the tumor appeared to invade the sacrum and project backward (Fig. 6).

Fig. p. b. Microscopic aspect of the tumor high power.

Surgical removal was undertaken. During the operation it was observed that the mass was lobulated and presented areas of softening. It was chiselled away from the sacrum but a complete removal was impossible because the sacrum was deeply involved.

The histological slides showed a tumor composed mainly of cartilaginous cells. The matrix was hyaline and very abundant, much of which was calcified. In some places there was myxomatous degeneration. No evidence of malignancy was observed.

At present, 7½ years after surgical removal the patient is in excellent general condition, works on his farm and has only occasional mild back pain.

The treatment of these tumors is total resection if possible. They usually do not respond to roentgen therapy. Good results after total removal have been reported by several authors particularly in tumors located in the neural arches (Peycelon and Aufrere, Ljachovitzky) provided no neurological complications are present and that removal is complete.

FIBROSARCOMA

Seven cases of fibrosarcoma were studied. The process was localized in the lumbar spine in 3 cases in the dorsocervical region in 1 instance. In the remaining cases the process had produced a destruction of the sacrum.

Fig 10 Localized destruction (arrows) of two lumbar bodies produced by metastasis from carcinoma of the breast.

The age of the patients ranged from 3 to 73 years. Six were males. A history of definite local trauma before the onset of symptoms was found in 3 cases. The first symptom was in accordance with their localization. The

Fig 11. a left, Osteolytic destruction of the posterior part of the second lumbar vertebra before treatment. b After x ray therapy and testosterone, some recalcification can be seen. Some osteoplastic nodules can be seen in upper and anteroinferior part of the second lumbar vertebral body.

Fig. 1a

cases involving the sacrum usually presented sciatic pain; those involving the lumbar spine usually developed low back pain; and in the 1 case involving the cervicodorsal region weakness of one hand was the initial symptom.

Fullness or presence of a mass in the para-vertebral region or on rectal examination was

Fig. 2a

Fig. 2b

Fig. 2. a, Collapse of lumbar vertebral body produced by metastatic hypernephroma. b, Microscopic aspect of the tumor.

present in 4 cases. Tenderness over the spine on palpation or percussion was found in 3 cases.

In the roentgenograms the lesion was seen to be purely osteolytic. It was confined to the vertebral bodies in 2 cases; to the neural arches in 1 case; to the whole vertebra in 1 case; and the sacrum and sacroiliac joint in the 3 remaining cases.

The clinical diagnosis was confirmed by aspiration biopsy in 2 cases; in the remaining ones by surgical biopsy or at autopsy.

Fig. 3b

Fig. 3. a, Perineural fibrosis involving the bodies and neural arches of the 4th, 5th, and 6th lumbar vertebrae. b, Microscopic aspect of the tumor. High power.

The end result in 6 cases is known to us. Two died shortly after admission. In the third case diagnosis was incorrect and two drainage operations were performed. Later on he was treated with x ray radiation and died 14 months after the onset of symptoms. The fourth case was treated only by means of x ray therapy after the clinical diagnosis had been confirmed by aspiration biopsy. The patient died 27 months after the onset of symptoms. The fifth case presented clinical signs of cord compression and it was necessary to perform a laminectomy. The patient died a few months after operation. Finally the sixth case has been followed for over 5 years and has had no recurrences. Although some authors have reported 5 year cures in cases of fibrosarcoma involving the spine (Avragnet and Duhem) their number is relatively small. A detailed report of our case seems justified.

This patient was a 57 year old male who 3 years prior to admission to the hospital started to have some pain localized in the middle of his back. One year later a lump the size of a silver dollar was noticed. The pain became more acute and the tumor increased in size. On admission local physical examination showed the existence of a swelling twice the size of a fist, just lateral to the spinous processes on the right side and extending from the tenth dorsal vertebra to the third lumbar. This mass was tender and fluctuant on palpation. Roentgenographic studies revealed the destruction of the pedicle of the first lumbar vertebra on the right side, the presence of a soft tissue mass extending down into the lower lumbar region and the existence of an area of calcification in the upper pole of the tumor (Fig 7a and b).

An aspiration was performed and myxoid material obtained. Microscopic studies confirmed the diagnosis of fibrosarcoma.

A few days later surgical removal of the tumor was undertaken. The mass was moderately well encapsulated lying in the angle formed between the spinous and the transverse processes, of the lower dorsal and upper lumbar regions. The tumor was adherent to the transverse processes of the lumbar vertebrae making it necessary to strip the periosteum of some of them in order to remove the tumor. Before suture, 8 radium needles and 3 milligrams of radium were placed in the walls. After operation patient received x ray therapy. At present 7½ years after surgical removal he is in good general condition and there has been no local recurrence.

CHONDROSARCOMA

In the case we studied the chondrosarcoma was localized in the dorsal spine.

This 65 year old male had a history of onset of sharp pain in his right upper abdominal quadrant 7 months before admission. At first this pain appeared in attacks occurring about once a week but progressively becoming more frequent. He lost 10 pounds. On physical examination gastrointestinal and genitourinary series were negative except for a nonfunctioning gall bladder.

One year later he started to complain of dull aches in the legs, soreness of the spine, poor bowel and bladder control and weakness of the legs. Physical examination on readmission to the hospital showed the presence of a spinal cord compression at the level of the eighth dorsal vertebra. Roentgenographic studies demonstrated the destruction of the vertebral body of the eighth dorsal vertebra.

A laminectomy was performed and a tumor compressing the cord was found and partially removed. It had invaded the eighth rib and the right part of the vertebral body. Microscopic studies showed the presence of a chondrosarcoma (Fig 8).

Following the laminectomy the patient received roentgen therapy with marked symptomatic relief of pain. However he died 14 months later.

OSTEOGENIC SARCOMA

The only patient with osteogenic sarcoma of the spine seen in this hospital was a 23 year old male admitted complaining of severe attacks of pain in the back of his neck. The pain was episodic at first but later became constant and radiated to the right arm. Physical examination showed all the clinical signs of cord compression at the level of the sixth cervical vertebra. Roentgenographic studies were negative. Exploratory laminectomy was performed and a tumor involving the fourth, fifth and sixth cervical vertebrae was found and only partially removed because much bleeding was encountered. The patient died shortly after the operation. At autopsy, it was observed that the tumor had completely invaded the lower cervical region.

Although microscopic slides are at present unavailable, the diagnosis of osteogenic sarcoma was definitely established at the time of the patient's death.

HODGKIN'S DISEASE

Four cases of proved Hodgkin's disease presented vertebral destruction. The process was localized either in the lower cervical or in the upper dorsal segment with the exception of one case in which there was a generalized vertebral involvement. The clinical manifesta-

Physical examination on readmission to the hospital showed the presence of a spinal cord compression at the level of the eighth dorsal vertebra. Roentgenographic studies demonstrated the destruction of the vertebral body of the eighth dorsal vertebra.

A laminectomy was performed and a tumor compressing the cord was found and partially removed. It had invaded the eighth rib and the right part of the vertebral body. Microscopical studies showed the presence of a chondrosarcoma (Fig 8).

Following the laminectomy the patient received roentgen therapy with marked symptomatic relief of pain. However he died 14 months later.

OSTEOGENIC SARCOMA

The only patient with osteogenic sarcoma of the spine seen in this hospital was a 23 year old male admitted complaining of severe attacks of pain in the back of his neck. The pain was episodic at first but later became constant and radiated to the right arm. Physical examination showed all the clinical signs of cord compression at the level of the sixth cervical vertebra. Roentgenographic studies were negative. Exploratory laminectomy was performed and a tumor involving the fourth, fifth, and sixth cervical vertebrae was found and only partially removed because much bleeding was encountered. The patient died shortly after the operation. At autopsy, it was observed that the tumor had completely invaded the lower cervical region.

Although microscopical slides are at present unavailable, the diagnosis of osteogenic sarcoma was definitely established at the time of the patient's death.

HODGKIN'S DISEASE

Four cases of proved Hodgkin's disease presented vertebral destruction. The process was localized either in the lower cervical or in the upper dorsal segment, with the exception of one case in which there was a generalized vertebral involvement. The clinical manifesta-

tions of these vertebral involvements were represented by radicular or local pain or by signs of cord compression. One case developed a complete block at the level of the second lumbar vertebra, requiring a decompressive laminectomy.

The roentgenograms demonstrated that the process usually involved the vertebral bodies and the transverse processes. The lesions were always osteolytic in character. The intervertebral disc appeared thinned in one of the cases.

All our cases were treated by means of x ray therapy. One patient had symptomatic relief for a period of 5 years. Roentgenographic follow up during this period of time showed complete arrest of the osteolytic process.

Autopsy findings were available in 2 cases. The spongy bone of the involved vertebrae was found to be replaced by a soft tumor. This tumor was spreading over the anterior surface of the vertebrae in one case and the spinal cord in the other. In not a single instance was spinal cord compression present. At some points, several tumoral nodules localized in the posterior mediastinum appeared to be invading the vertebral bodies.

MULTIPLE MYELOMA

Ten proved cases of multiple myeloma involving the spine were studied. Autopsy findings of 7 were available.

The age of the patients at the onset of symptoms was between 40 to 75. Eight of the patients were males. While under the care of this hospital, 9 of them died. The interval between the onset of symptoms and death ranged from 4 months to 6 years. From a clinical standpoint, there seemed to be some acute forms of the process capable of producing death in a short time.

Repeated investigations for Bence Jones proteins were performed in 4 cases and a positive finding was obtained in only 1 instance. Among the remaining cases in which these proteins were not investigated, we found that urinary albumin was present in 4 cases.

The main clinical signs were a sensation of marked fatigue and extreme lassitude that eventually confined the patient to bed. Radic

ular pains along the distribution of peripheral nerves and pain on pressure over ribs, pelvis, and skull were frequent manifestations. Blood studies usually showed the presence of marked anemia sometimes accompanied by leucocytosis.

Roentgenographic findings varied from the appearance of a marked osteoporosis without definite destructive areas to the presence of multiple and well circumscribed osteolytic lesions.

On microscopical examination it was found that the normal elements of the osseous marrow were replaced by plasma cells or by small cells with hyperchromatic nuclei and scanty pale protoplasm which resembled plasma cells.

At autopsy multiple scattered grayish yellow or hemorrhagic nodules were found in the spine or surrounding tissues. Tumoral tissue was present in the ribs, in the vertebral bodies or in the neural arches. In some cases the tumoral neoformation invaded the neural canal or the erector spinae masses. In 1 case the cauda equina was compressed.

SOLITARY MYELOMA

Instances of solitary myeloma producing destruction of a vertebral body have been reported by Wright, Peyton, Paul and Pohle, Pasternack and Waugh.

Among our studied 10 cases of multiple myeloma we found 2 cases in which the lesion could be considered circumscribed to the spine during the early stages of the disease. In 1 case the tumor produced compression myelitis and a laminectomy was performed (Fig 9). This patient died of secondary infection following operation and consequently we disregard the fact that the condition would have become generalized. In the second case the lesion was confined to one vertebral body during the early stages. As the patient's general condition was excellent and improved following the use of a body brace the condition was diagnosed as Kummell's disease. However roentgenograms taken a few months later revealed the presence of a marked loss of calcium and mottling of the thoracic cage. At autopsy two vertebrae and one rib were removed. A multiple myeloma was responsible for their destruction.

Carcinoma of the prostate. Our patients with metastatic lesions from carcinoma of the prostate were between 44 and 71 years of age. The bone metastases were localized in the lumbar spine in 2 patients in the dorsal segment in 3 patients. There was a generalized involvement of the spine and pelvis in the 3 remaining patients. The roentgenograms showed that the metastatic lesions were osteoplastic in all of them.

An evaluation of the results of roentgen therapy could be made in only 4 patients. One patient was completely relieved of pain. 2 patients had partial relief. 1 patient had no relief of pain. This last patient was later treated with stilbesterol and 16 months after onset of this treatment the patient feels excellent and has gained weight.

In none of our studied cases were the values of acid phosphatase (Gutman, Sproul and Gutman, Huggins and Hodges, Gutman and Gutman) recorded.

Hypernephroma. Three patients with hypernephroma developed metastasis in the spinal column. The metastatic lesions from hypernephroma were localized in the dorsal spinal segment in one case and in the lumbar spine in the 2 others. A pathological fracture was the first clinical sign in 1 patient. The patients were all over 50 years of age.

In the roentgenograms the lesions were seen to be purely osteolytic. The clinical diagnosis was confirmed at autopsy in 2 cases and following laminectomy in the 1 remaining. In the last case the tumor had produced a complete block at the level of the first lumbar segment and a complete destruction of the vertebral body (Fig. 12 a and b).

Ewing's tumor. A boy 16 years old with Ewing's tumor of the right femur developed generalized metastasis involving the other femur, the skull and the sacrum. The diagnosis was confirmed by biopsy of a nodule under the scalp. The sacral lesions were purely osteolytic.

Chondrosarcoma. Our case of metastatic lesion produced by chondrosarcoma is interesting because it appeared in a patient suffering from multiple cartilaginous exostosis. It was not until the patient was 48 years old that several exostoses attached to the femur under

went malignant degeneration. The patient was treated by means of roentgen therapy for 5 years with only symptomatic relief. At the end of this period, he suddenly developed signs of cord compression and died following a laminectomy. During the operation it was observed that the cord was compressed by a mass arising from the eighth dorsal vertebra. This mass could have been a primary exostosis that had also undergone malignant degeneration, but because of the patient's clinical history it was classified as a metastatic lesion.

Bronchogenic carcinoma. A case of bronchogenic carcinoma was studied with a partial destruction and collapse of the body of the fourth lumbar vertebra due to a metastatic lesion. The patient was a 39 year old male with a history of low back pain for 5 months, cough and difficulty in swallowing solid food for 3 months. The roentgenograms showed, in addition to the vertebral destruction, a marked mediastinal enlargement. The patient was subjected to roentgen therapy and died 3 months afterward.

Carcinoma of the skin. Vertebral destruction secondary to carcinoma of the skin appeared in a male 62 years old who 6 years prior to admission had developed a well differentiated epidermoid carcinoma over the right temple. X ray therapy was administered and the skin lesion healed. Four years later he noticed a small lump 1 centimeter in diameter in front of his right ear. Eleven months before admission he suddenly developed pain in the upper dorsal spine. Roentgenograms taken on admission showed a compression of the sixth dorsal vertebral body. X ray therapy was again administered without relief of pain. The patient died 1 year later.

Carcinoma and fibrosarcoma of the cervix. Both types of tumors produced osteolytic lesions in the vertebral bodies accompanied by pathological fracture very similar to the lesions seen in cases of carcinoma of the breast metastasizing to the spine.

Osteogenic sarcoma. Sarcomatous lesions associated with elevated temperature and increased white count may sometimes be confused with inflammatory conditions. The differential diagnosis in our case was based on the clinical history.

A 34 year old male was admitted in 1936 complaining of marked pain in the right hip. The patient stated that in 1922 a lump had appeared over the second metacarpophalangeal joint of his right hand. Between 1922 and 1930 this tumor was removed 5 times because of repeated recurrences. Finally in 1930, the finger was amputated. However there was a local recurrence of the tumor and in 1931 the right forearm was amputated 3 inches below the elbow. In 1934 the axillary glands became enlarged and were removed. Microscopical studies throughout confirmed the presence of osteogenic sarcoma.

The patient was asymptomatic until September 1936 at which time he developed sharp pain in his right hip. The roentgenograms at this time showed marked destruction of the hip joint. A hip spica was applied to control the pain. In February 1937, the patient developed sudden severe pain between the shoulders. A few days later there was sudden loss of bowel and bladder control, numbness from the nipple line down and severe pain on coughing and sneezing. The following day flaccid paralysis with complete motor and sensory loss was present. Roentgenograms demonstrated a paravertebral soft tissue shadow. The patient was running a temperature of 102-103 degrees and his blood count was 68,000.

An attempt to aspirate the paravertebral mass proved unsuccessful. A laminectomy was performed and a tumor 2 1/4 inches in diameter moderately firm, extremely friable, fish flesh appearance and not encapsulated was found. The vertebral bodies appeared very rough and invaded.

Following removal, roentgen therapy was instituted. The patient died 1 month after surgery.

VERTEBRAL CHANGES FROM TUMORS ARISING IN THE VERTEBRAL CANAL

Vertebral changes secondary to tumors arising in the vertebral canal have been described by several authors (Rix and Geschickter). Among our material we found 2 such cases. In 1, there was a meningioma that had produced widening of the interpedicular space of one vertebra. The other was a case of perineurial fibroma.

Perineurial fibromas have received different denominations (neurinoma solitary neurofibroma, gloma peripherique). According to Mallory and Penfield, they arise from the connective tissue surrounding the nerve fibers, and do not contain nervous elements.

They may be intrameningeal or extrameningeal or in some cases develop along a nerve root, thus producing the so called dumb-bell tumors. In the cervical and dorsal regions these tumors usually produce a progressive erosion of the laminae and give origin to great

extravertebral masses. However, in the lumbar region, they frequently remain intrameningeal throughout, and produce marked erosion of the vertebral bodies and neural arches (Camp Adson and Shugrue) (Fig 13).

The evolution is usually very slow giving rise to clinical signs of progressive cord compression if they remain intrameningeal.

CERVICOMEDIASTINAL AND MEDIASTINAL CYSTIC HYGROMAS

ROBERT E. GROSS M.D., F.A.C.S., and ELLIOTT S. HURWITT M.D., Boston, Massachusetts

CYSTIC hygroma of the neck is a well recognized entity. Gross and Goeringer in 1939 reported a group of 27 patients bringing the total number in the literature at that time to approximately 225 cases. Although an uncommon lesion there are doubtless a considerable number of these cases which are not recorded in the literature. In 1946 twelve cervical hygromas were excised at The Children's Hospital. In view of the marked tendency of these cystic masses to involve adjacent structures by direct extension one might anticipate a relatively high incidence of cervicomediastinal lesions. However a review of the literature reveals only 19 cases of cervicomediastinal hygromas. Intrathoracic hygromas without involvement of the neck, are even more rare. Sanes, MacManus and Scatchard reporting a case of cystic lymphangioma of the mediastinum in 1945, were able to find only 8 published apparently similar cases some of these on close inspection were probably not true hygromas. The lack of uniformity in the treatment of cervicomediastinal and mediastinal hygromas prompts this review of the subject with the report of 3 additional cases.

REPORT OF CASES

CASE 1. No 203002 E. F. a 14 month old white girl, was admitted to The Children's Hospital on April 11, 1945. A mass had been present in the left side of the neck since birth and this had increased steadily in size. Physical examination revealed a well nourished child with normal development for her age. There was a large cystic swelling on the left side of the neck (Fig 1) in the center of which was a small hard portion about 2 centimeters in diameter. The entire mass greatly increased in size when the child cried, and it decreased in size during inspiratory efforts. There were no abnormal physical findings related to the thorax or to the remainder of the body.

Laboratory data. The white blood count was 10,300. Urinalysis was negative. X ray and fluoroscopic examination from the Surgical and Pathological services of the Children's Hospital and the Peter Bent Brigham Hospital, and the Departments of Surgery and Pathology of the Harvard Medical School,

examination showed a large round soft tissue mass of homogenous density in the left, upper part of the chest (Fig 2). On expiration the mass was most prominent in the neck. On inspiration the major portion of the mass could be seen in the left side of the thorax. On digital compression of the cervical mass the mass within the thorax produced a fairly marked shift of the trachea and mediastinal structures to the right. There was no definite abnormality of the lungs.

First operation. On April 13, 1945 under avertin ether anesthesia, cervical exploration was performed. A large cystic hygroma in the left side of the neck was dissected out cleanly. It soon became apparent that the mass was a multilocular structure. There were 3 main components: one going to the base of the skull, one extending down beneath the left scapula, and a third extending into the mediastinum probably to the level of the heart. It was impossible to remove all intrathoracic portions of the cystic hygroma through this exposure. As far as possible the some remaining ones were swabbed with tincture of iodine in the hope of producing sclerosis. A small rubber drain was inserted into the mediastinum and the cervical wound closed about the drain. Postoperatively considerable amounts of fluid were expressed from the cervical wound daily for about a week. The child was discharged from the hospital markedly improved on the eleventh postoperative day.

Pathology report. The specimen consisted of 3 red yellow soft pieces of tissue containing multiple clear walled cysts filled with a yellow fluid. The cysts varied in size from 1 to 1.2 centimeters in diameter. Microscopic examination revealed multiple cystic, endothelial-lined spaces. These varied from large irregular cavities to small cysts (Fig 3). Some contained smooth muscle in their walls; others had only connective tissue. Supportive structures contained variable amounts of fat. The findings were typical of cavernous lymphangioma (cystic hygroma).

Second admission. On August 6, 1946 16 months after the first operation the child was readmitted. She had made an uneventful recovery and had been relatively asymptomatic except for a poor appetite and slow weight gain until May 1946 at which time the mother noticed a swelling over the left upper chest posteriorly. The swelling appeared rapidly and was associated with some pain in the left arm. Physical examination disclosed a well healed left transverse cervical incision just above the clavicle. Percussion of the chest was normal except for a small area of dullness just to the left of the sternum. In the

20	Gross and Harvitt Case	1948	4 mos.	F	(1) Resection of cervical portion (2) Resection of mediastinal portion (3) Resection of subscapular portion	Improved.
21	Case	1948	7 mos.	F	Resection of cervical portion. Incision of mediastinal portion	Improved.

*Two cases reported by Lenson in 1931 presumably had been included in the previous report by Fagin (Personal communication, Mayo Clinic.)

left posterior chest wall was a freely movable ovoid cystic mass measuring about 5 centimeters in its long axis (Fig. 1).

Laboratory data. The red blood count was 3,680,000 and the hemoglobin 86 per cent. Urinalysis was normal. X-ray examination of the chest showed a persistence of the shadow in the left upper portion of the chest. This extended from the superior mediastinum out into the apex of the left pleural cavity.

Second operation. On August 7, 1946, under cyclopropane anesthesia, thoracic exploration was performed. The left pleural cavity was entered through

the third interspace anteriorly. In the upper part of the pleural cavity was a cystic mass somewhat larger than a golf ball, some portions of it were quite thin, whereas others appeared to be distinctly thickened and scarred. The mass presented below the thoracic inlet and extended along the lateral aspect of the mediastinum to the root of the lung; the lung was not involved. The overlying parietal pleura was incised and the phrenic nerve dissected away from the anteromedial border of the hygroma. The vagus nerve was not adherent to the hygroma. The mass was dissected free from the aorta, the left subclavian

Fig. 1 Case 1. Above, Photograph of 14 months old girl with a large cervicomedistinal hygroma. The cervical swelling was prominent during crying or straining, but most of it disappeared when the child was quiet, especially during inspiratory periods. Below Photograph 16 months after surgical removal of cervicomedistinal hygroma, now showing development of a posterior thoracic (subscapular) hygroma. (Compare with Fig. 5)

artery and the left innominate vein. The internal mammary artery and vein were divided and sections of them were removed with the hygromatous specimens. At the thoracic inlet some small cysts were cut across and minute bits of hygromatous tissue were left in place to avoid running the risk of injury to

Fig. 2 Case 1. Above Roentgenogram of the cervicomedistinal hygroma, showing the mass of uniform density in left upper part of the thorax and with a slight displacement of mediastinal structure to the patient's right. Below Roentgenogram, following removal of thoracic hygroma.

important anatomical structures at the base of the neck. The chest wall was closed in layers the lung being expanded before the closure was completed. The patient stood the procedure extremely well and was returned to bed in good condition. Convalescence was uneventful. The wound healed by primary union.

Pathology report The specimen consisted of a multicystic reniform piece of tissue measuring 5 by 4.5 by 1.5 centimeters. Microscopic examination revealed multiple cysts fatty and connective tissue and numerous small blood vessels (Fig. 4). In the supporting tissues there were small nests of lymphocytes. In contrast to the cervical cysts which had been previously examined this thoracic specimen showed a much more abundant connective tissue in the walls of the cysts.

Third operation On August 17 the cystic mass in the left posterior chest wall was removed. This was situated deep to the levator scapulae muscle and lay on the rib cage, running out beneath the scapula. It had only a filmy attachment to the underlying

Fig 5. Case . Photomicrographs of cervical component of hygroma. Above, Low power showing the multilocular architecture. Below, Higher power indicating the character of cyst wall.

ribs and could be removed without difficulty. The patient tolerated this last procedure extremely well and was discharged from the hospital on the following day.

Pathology report. The specimen consisted of a cystic irregular egg-shaped mass measuring 4 by 3 by 1 centimeter (Fig. 5). The capsule consisted of dark gray fairly tough tissue. The cyst was filled with thick, dark red brown fluid. On microscopic examination a multicystic mass was seen, with a dense interlacing fibrous stroma. In some areas were small nodules composed of endothelial cells, with a rather high degree of cellularity (Fig. 6). There was a light infiltration of lymphocytes. Numerous large vacuolated phagocytes were present, some containing large amounts of hemosiderin, others being laden with lipid material. The findings were those of a cavernous and capillary lymphangioma and also a more rapidly growing lymphangioblastoma.

Follow-up note. Examination of the patient in November 1947 showed all the wounds to be well healed and the patient to be in good condition. There was no swelling in the neck or in the left scapular region. A roentgenogram of the chest was essentially normal.

Fig 6. Case . Photomicrograph of mediastinal component of the hygroma. Above, Low power revealing the intimate relation of the cysts to large blood vessels. Below, Higher power showing the endothelial lining of the cystic cavity.

CASE 2: No. 301086 b. M., a 7 month old white female was admitted to the Children's Hospital on January 8, 1946. The baby was born with a small nubbins of cystic tumor on the right side of the neck, which had increased rapidly in size until now it was larger than a goose egg. The parents had noticed that the mass increased in dimensions whenever the baby cried and it would almost disappear when the baby inspired. For 2 weeks prior to admission the baby had vomited frequently and had lost 4 pounds. On physical examination a lobular cystic mass was noted on the right side of the neck measuring about 10 centimeters in diameter (Fig. 7). This was soft and could be compressed and held down within the normal contour of the neck.

Laboratory data. Film and fluoroscopic examination showed a large round soft tissue mass of homogeneous density in the right side of the neck. This extended through the circle of the first rib into the mediastinum and pleural cavity on the right side (Fig. 8). On deep inspiration the mass descended almost entirely into the chest and during expiration it was very prominent in the neck. There was a moderate shift of the esophagus and trachea to the left. In a lateral view of the neck a considerable amount of the hygroma lay behind the pharynx. The trachea and larynx were markedly displaced forward (Fig. 9).

Fig 5 Case 1 Cystic mass removed from posterior chest wall (subcapular area)

Hospital course Because of an intercurrent respiratory infection and otitis media, operation was deferred and chemotherapy was given.

Operation On February 12 1946 operation was performed under ether anesthesia. A long transverse incision was made in a fold of the skin over the presenting mass. The platysma sternomastoid and ribbon muscles as well as the omohyoid were divided. A large irregular smooth multiloculated hygroma was encountered. During the operation there was a good deal of tracheal compression and intermittently there was obstruction of the airway. It seemed wisest to open the main cyst in order to collapse it. When this was done several ounces of thin bloody fluid escaped and the respiratory difficulties completely disappeared for the remainder of the procedure. There were several large smooth walled cavities which intercommunicated all of which collapsed when the main cyst was opened. By digital examination one could feel a finger-sized projection upward along the carotid vessels to the base of the skull. There was also a large finger-sized projection behind the carotid sheath extending posteriorly well behind the mastoid region. Another projection went downward into the thorax and a palpating finger in the opened cyst could be passed inferiorly as far as the lung root. The mass filled about the upper third of the pleural cavity. With meticulous care all of the cyst membranes in the neck were dissected out. The removal of the membrane in the thorax seemed too hazardous because of the danger of damaging adjacent important anatomical structures such as the vena cava. Hence the entire lining of this mediastinal portion of the hygroma was diffusely swabbed with tincture of iodine in the hope of destroying its lining membrane. A small rubber wick was led down into this cavity to allow for the escape of any fluid and thus permit coalescence of the cyst walls. The neck wound was closed in layers about the drain.

Postoperative course The patient began taking fluids on the second postoperative day. She took increasing amounts of feeding without difficulty and gained 1 pound in the first 2 postoperative weeks. On 3 occasions accumulations of cystic fluid in the

Fig 6 Case 1 Photomicrographs from specimen shown in Figure 5. Above, The transition from simple hygroma and cellular lymphangioendothelioma is evident. Below, From endotheliomatous area, showing cellular portions differentiating into capillary spaces.

cervical region were aspirated approximately 5 cubic centimeters of reddish fluid being obtained each time. The child was discharged from the hospital on the eighteenth postoperative day afebrile and in good condition. She was last examined in November 1947 at which time she had gained weight and looked very well (Fig 9). The neck appeared normal. Roentgenogram of the chest showed only a slight thickening on the right side of the superior mediastinum.

CASE 3 No 12277 R.F. A 32 year old white, male salesman was admitted to the Peter Bent Brigham Hospital on December 1 1943. Seven weeks previously attempting to enlist in the Navy he was found to have a mediastinal shadow by routine x ray examination. He had been completely asymptomatic. On physical examination an area of decreased breath sounds and dullness was found to the right of the sternum from the third to the fifth interspace anteriorly extending laterally for about 5 centimeters

Fig. 7. Case 1. Above, Photograph of 7 months old girl with right-sided cervico-mediastinal lymphoma. The cervical mass varied in size during respiratory movements. Below, Lateral roentgenogram of neck, showing marked anterior displacement of trachea.

Fig. 8. Case 1. Above, Preoperative roentgenogram during inspiration, demonstrating the dense mass in right upper part of the thorax. Middle, Preoperative roentgenogram during expiration showing displacement of greater part of the mass up into the neck. Below, Postoperative film after trans-cervical cauterization of mediastinal lymphoma. The slight remaining shadow is believed to be dense sclerosed tissue.

No cardiac abnormalities were elicited. The blood pressure was 8/50.

Laboratory data. White blood count was 7,600; red blood count, 4,560,000; hemoglobin, 80 per cent

urine normal. The blood Hinton test was negative. X-ray examination of the chest, including roentgen-

Fig. 9. Case 2. Photograph following surgical excision of the cervical hygroma and transcervical chemical sclerosis of mediastinal projections of the mass.

okymography of the heart showed a discrete shadow in the right anterior mediastinum suggesting a benign tumor or cyst (Fig. 10).

Operation. On the second hospital day, under positive pressure ether anesthesia, operation was carried out. The right pleural cavity was entered anterolaterally through the fourth interspace after dividing the fourth, third, and second costal cartilages. A cyst the size of two clenched fists bulged from the anterior mediastinum toward the right and projected into the pleural cavity. It lay on the pericardium to which it was lightly adherent. It reached posteriorly as far as the phrenic nerve and extended from the diaphragm well up to the great vessels. The mediastinal pleura which covered it was divided and the cyst was freed from the mediastinal structures; there was very little bleeding during the dissection. The chest wall was repaired in layers; the right lung being completely expanded before completing the wound closure.

Pathology report. The specimen (Fig. 11) consisted of a large cystic mass measuring 13.5 by 9 by 6.5 centimeters. (Because of the escape of fluid, the original size had been larger than this.) The mass was irregularly round in shape and soft in consistency. Its external surface was pinkish-gray in color and presented a few loose fibrous adhesive tabs. In general the walls were thin, but in a few places they were thick and rather tough. The contained fluid was clear and amber colored. The interior of the cyst showed a multilocular structure, the various compartments of which communicated with one another. Microscopic examination showed a typical hygroma.

Fig. 10. Case 3. Preoperative roentgenogram of mediastinal hygroma in a 32-year-old man. Right border of the mass is slightly lobulated, smoothly outlined, and obscures the right border of the heart.

the walls of which were formed by loose connective tissue, the spaces being lined by an endothelium.

The postoperative course was uneventful. The sutures were removed on the fifth day and the patient discharged afebrile and asymptomatic on the tenth day. X-ray examination on December 11 showed that the large mass previously noted on the right border of the heart had been completely removed.

The patient was last examined on February 21, 1944, by which time he had gained 27 pounds; he ap-

appeared to be in excellent health. Three years later, upon application for life insurance the patient had no complaints and there were no abnormal physical findings.

ETIOLOGY

These cystic hygromas may properly be classified among the congenital malformations. The lymphatic system is derived by a growth and coalescence of the lymphatic sacs or buds and their extensions. These buds develop either as outpocketings of the venous system (Sabin) or they are formed from mesenchymal deposits (Huntington). An arrest or pinching off of any part of these processes may predispose to the formation of cystic structures with the capacity for continued independent growth. The most common primary sites of hygromas, namely the cervical axillary and much less frequently the inguinal regions coincide with the areas in which the lymphatic buds are known to be normally present in embryos.

The mechanism whereby hygromas may be found in the mediastinum either with or without a cervical component has not been completely explained. Egler and Michaelis have suggested that intrathoracic lymphangiomas, tons cysts or cystic hygromas have grown downward from the neck. In those cases with frank involvement of both the neck and the mediastinum such an extension would seem obvious. There are however mediastinal hygromas with no demonstrable cervical connections. In these cases while it is conceivable that a cervical component might have been

present originally the possibility of an independent origin within the mediastinum must also be admitted.

PATHOLOGY

Hygromas are characteristically thin walled cystic structures lined by endothelium. Although occasionally unilocular for the most part they are multilocular the subsidiary cysts having a variety of sizes and shapes. Many of the cysts may intercommunicate whereas in other areas septation may be complete. The multilobulated appearance of the cysts in the gross is caused by these septa. Puncture of one portion of the mass with release of fluid may or may not result in collapse of the entire structure, depending on the degree of completeness of compartmentation. The fluid is usually thin and colorless when there has been superimposed hemorrhage the fluid may be xanthochromic or frankly bloody.

A variety of structures may be incorporated in different portions of the cyst walls ranging from connective tissue and strands of smooth muscle to fat blood vessels and nerves. The most plausible explanation for the presence of foreign elements such as nerves is that suggested by Goetsch. The cysts enlarge by a process of endothelial sprouting. These buds extend along tissue planes insinuating themselves between and around any structure in their path, and the buds subsequently enlarge to sizable cysts. In this way a vessel or nerve, actually surrounded by cystic prolongations, may appear to be traversing the cystic mass.

It is this intimate involvement of regional tissues that may cause almost insurmountable technical difficulties in surgical dissection.

A distinction between cystic hygromas and cavernous lymphangiomas has been postulated on the basis of the widespread occurrence of the latter in various regions of the body without the development of features which have been described as characteristic of hygromas. While such a distinction may be valid in the case of lymphatic malformations in superficial areas of the body, it can hardly apply to the mediastinum. It is our belief that the terms cavernous lymphangioma and 'cystic hygroma' describe the same pathologic process or malformation but that the latter merely indicates a much greater tendency to development of compartments of large size.

In 1940 Lambert, during a discussion of the etiology of thin walled thoracic cysts pointed out the necessity of distinguishing between the multiloculated hygromas and other varieties of mediastinal cysts. He described the hygroma as being composed of a conglomerate mass of individual cysts of differing sizes intimately associated with various structures in the vicinity and presenting no sharp line of cleavage from regional organs. These were contrasted with the simple monolocular mediastinal cysts situated in relation to the pericardium which shell out readily. Lambert considered the latter so-called endothelial or celomic cysts to come from embryologic derivations in the formation of the pericardium and concluded that some of the cases previously regarded as mediastinal cysts of lymphatic origin probably belonged to this category. The reports of Dufours and Mourrut, Pickhardt and of Eigler are examples in point.

CLINICAL FEATURES AND DIAGNOSIS

Hygroma of the neck usually is noted at birth although a later onset is sometimes seen. The soft poorly defined swelling is most commonly present in the posterior cervical triangle although the mass may appear anywhere from just above the clavicle to beneath the mastoid process. Extension from the neck to the axilla or into the floor of the mouth has been noted as has an engirdling prolongation beneath the mandible from one side of the

neck to the other. Aside from the unsightly appearance of such a mass associated symptoms are usually few unless there should be sufficient displacement of the trachea or esophagus to cause interference with breathing or swallowing. When a cervical hygroma is small it must be differentiated from other causes of cervical swelling such as a branchial or thyroglossal cyst, lipoma, deeply situated hemangioma, lymphadenopathy or herniation of the lung. When a cervical hygroma is large there is little difficulty in recognizing it because of its great size, its thin walls, its translucent character and its soft flaccid consistency.

Recognition of a cervicomedial hygroma is made by physical examination of the cervical swelling supplemented by roentgenographic examination of the chest. A soft tissue shadow in the neck connecting with a mass in the mediastinum or upper pleural cavity should suggest strongly a common etiologic background. Periodic fluctuation in size has frequently been observed in cervical hygromas. This is even more characteristic of the combined cervicomedial lesions in which the cervical component may be seen to increase in size during acts of crying, grunting or expiratory efforts and conversely to decrease in size during inspiratory movements. X-ray film and fluoroscopic examination may show descent of the mass into the mediastinum on inspiration whereas there is a prominence in the neck during expiration (Fig. 8). Lateral and anteroposterior films of the cervical region will reveal the direction and extent of displacement of the regional structures. Although the thoracic prolongation may extend only into the superior mediastinum, descent to a level as low as the eighth thoracic vertebra has been recorded by Arnheim. There has been no consistent correlation between dyspnea or dysphagia and the presence of a mediastinal component, these symptoms being an indication of the degree of mechanical compression which is present in a given case.

The finding of chylothorax by Swift and Neuhoef associated with a cervical hygroma, and suggesting lymphangiomatous involvement of the thoracic duct is unique. These authors again point out the relationship between an upper respiratory infection and the

onset of acute symptoms in a case of hygroma. In a young subject a hygroma may become the focal point for the development of either a severe regional infection or a widespread sepsis, and constitutes a strong reason for instituting therapy before such complications can occur.

Cystic hygromas which have been confined to the mediastinum have usually been discovered either at autopsy or as unanticipated findings during x-ray examinations. This lack of symptomatology is probably related to the soft and yielding nature of the cysts which can obtain considerable size without giving sufficient pressure on regional organs to produce symptoms. An exception to this generality is provided by the report of Skinner and Hobbs who described a boy with dyspnea, orthopnea, nonproductive cough and "tightness" in the chest.

While the roentgen film may demonstrate a slightly lobulated, smoothly outlined mass, it is usually not possible by this means to distinguish hygromas from other benign tumors or cysts of the mediastinum, such as duplications of the esophagus, bronchial cysts, dermoids and teratomas, pericardial celomic cysts or tumors of the thymus gland (Laipply).

As the result of the roentgen survey of millions of young men and women during the war years, one might have expected the detection of an appreciable number of mediastinal hygromas. In this light it is surprising to note that Blades in his report of 100 patients with mediastinal tumors collected from various Army chest centers found no hygromas; it is possible that some of the pericardial cysts included in his series might have been hygromas. The publication by Watson and Diamond (31) on surgical thoracic tumors in Navy personnel lists only one cystic hygroma. (The fact that a mediastinal shadow constituted a lesion which disqualified a subject from military duty may have been an explanation for the rare appearance of thoracic hygromas in the previously mentioned series which were gleaned from military personnel.)

TREATMENT

The presence of an unsightly mass in the neck of a child provides an obvious source for

parental anxiety, and it is for cosmetic reasons that a surgical consultation is most frequently requested. In more rare cases the presence of acute symptoms resulting from compression of mediastinal structures or of the cervical part of the trachea demand immediate surgical intervention. Arnheim reported a case in which relief from asphyxia was so imperative that operation was performed by Neuhoef immediately after admission to the hospital with the child in a sitting position and without the use of inhalation anesthesia.

In addition to the cosmetic considerations and to the occasional relief of respiratory embarrassment, it is important to remove hygromas to prevent complications which are so apt to occur in the untreated lesions. Hygroma frequently become infected in the course of respiratory infections. While such infections may subside under chemotherapy or after incision and drainage, the risk of an overwhelming local or blood stream infection is great. One of Singleton's patients (Case 28) died of infection in the mediastinal portion 10 months after the cervical component had been resected. While it is true that infection is sometimes followed by local fibrosis and disappearance of the mass, such a favorable outcome is seldom encountered and it does not justify an attitude of expectant treatment. Spontaneous or posttraumatic hemorrhage into a cyst may result in marked distention of the same, give sudden appearance of tracheal compression and lead to a surgical emergency. While the occurrence of malignant change in a hygroma has not been reported, this theoretical possibility adds another indication for prophylactic therapy.

There has been little difference of opinion concerning the proper approach to the lesions which are confined to the mediastinum. Exploratory thoracotomy offers the surest means for making a differential diagnosis and certainly gives the best opportunity for definitive treatment. Fortunately, mediastinal hygromas can usually be excised with little difficulty because well developed tissue planes around the cysts facilitate their enucleation. Certainly when a hygroma bulges well out into either pleural cavity, its surgical removal is not apt to be difficult. However, when a cystic

mass insinuates itself between mediastinal structures the dissection might be hazardous—a fact commented upon by Sanes and his associates when dealing with a hygroma lying between the trachea and esophagus. In treating hygromas one must be always mindful of the excellent studies of Goetsch when pointed out the tendency of a hygroma to enlarge and envelop structures (particularly nerves and blood vessels) which lie in its path. Thus nerves such as the vagus and phrenic may become completely surrounded by hygromatous tissue. To maintain the integrity of such nerves it is frequently necessary to leave minute bits of hygromatous tissue along their surfaces but this does not necessarily militate against a successful outcome since an extensive experience with surgical treatment in cervical hygromas has convinced us that small remaining islands of lymphangiomatous tissue will probably become sclerosed and will not give rise to subsequent troubles.

Cervicomediastinal hygromas are apt to be much more difficult to treat than are those cysts which are situated completely within the thorax. Provided there are no complicating factors which require immediate attack on the intrathoracic portion the combined lesions are best handled by first directing attention to the cervical part, which should be treated by meticulous dissection and removal of the cyst and cysts having due regard for preservation of important anatomical structures. This choice of action provides the advantage of being able to continue the dissection down through the thoracic inlet to remove all or part of the hygroma which resides in the chest. The feasibility of this technique was commented upon by Eloesser, Martin and Lelong and Swift and Neuhof. It is further indicated by the favorable use in our first and second cases. If the hygroma has previously made a large opening through the thoracic inlet this provides an avenue of considerable width for carrying the surgical dissection downward to remove the intrathoracic projections provided the latter are not too large and are not attached to mediastinal viscera. Under favorable circumstances it might be possible to remove all of the intrathoracic part of the hygroma. More frequently it will be found that considerable

remnants remain within the chest and can be treated by (1) leaving them for a more adequate and a wider exposure through a subsequent thoracotomy (our case 1), or (2) continuing the initial operation by introduction of sclerosing agents down through the cervical wound (our Case 2). By this latter technique remaining cysts in the thorax can be broken into (via the cervical wound) and can be swabbed out with some irritating substance (such as tincture of iodine) to destroy the lining membranes. If such cauterizing substances have been used a soft rubber drain should be led down into the depths of the wound and left in place as long as there is any drainage in the postoperative period. (Failure to insert a drain will almost certainly be followed by postoperative reaccumulation of fluid within the cystic spaces and a reappearance of a smooth lining in many of them. In contrast the institution of external drainage will allow the inflamed walls of the cavities to coalesce and the spaces will thereby be obliterated.)

While we recommend treatment of cervicomediastinal hygromas by (1) separate operations in the neck and thorax and (2) by excision of the cervical portion and simultaneous sclerosis of the intrathoracic part—and have been completely satisfied with the result in either instance—it is well to call attention to the favorable results reported by Singleton and Goetsch wherein excision of the cervical portion was followed by x ray therapy to the mediastinum and also the procedure described by Pirtmann wherein radon seeds were applied to the mediastinal remnants.

SUMMARY AND CONCLUSIONS

The clinical and laboratory findings of cervicomediastinal and mediastinal hygromas have been reviewed. The successful management of 2 additional cases of cervicomediastinal lesions and 1 mediastinal cyst is reported. The cervical portions of hygromas are best treated by a meticulous dissection and removal of the cystic structures. Whenever possible treatment of the thoracic lesions is preferably done by complete extirpation of the presenting mass. Under some circumstances a cervicothoracic hygroma can be treated by

surgical excision of the cervical portion and transcervical approach to the intrathoracic portion the latter being treated by intense chemical sclerosis followed by external drainage. If such therapy is followed by persistence or recurrence of the intrathoracic component thoracotomy for excision of the remaining hygroma is indicated.

URETHRAL CARUNCLE

JAMES K. PALMER, M D JOHN L. EMMETT, M D and JOHN R. McDONALD M D
Rochester Minnesota

URETHRAL caruncle was first described by Sharp in 1750. Since his first description of this condition there has been much controversy concerning its etiology, pathology, classification and treatment. This diversity of opinion concerning a clinical entity which is so common stimulated our interest to investigate this subject. Accordingly we have made a clinical and pathologic study of 120 cases of urethral caruncle. The results of this study together with a review of the literature on this subject, form the basis of this paper. Inasmuch as a complete review of the literature on this subject has not been made for a number of years, our review has been made comprehensive.

REVIEW OF THE LITERATURE

Embryology and anatomy According to Arey the caudal segment of the cloaca that separates from the rectum becomes the primitive urogenital sinus. In the female the originally short neck between the bladder and the urogenital sinus elongates into the permanent urethra.

The gross anatomy of the female urethra is well described by Williamson and Atlee.

The female urethra is a narrow membranous canal about 4 centimeters long, extending from the internal to the external urethral orifice. Its diameter when undilated is about 6 millimeters. However the caliber is not uniform the urethra being somewhat fusiform in shape. It is capable of great dilatation. The female urethra is located behind the symphysis pubis imbedded in the anterior wall of the vagina, and its direction is obliquely downward and forward; it is slightly curved with the concavity directed forward.

The external urethral orifice is usually shaped like an inverted V and is situated di-

rectly in front of the vaginal opening and about 2.5 centimeters behind the glans clitoridis on the summit of a small eminence. Around the meatus are seen a number of small apertures which are the openings of the periurethral glands. Skene's glands usually open on the floor of the urethra some little distance from the meatus. Each aperture is surmounted by a small hoodlike fold of mucous membrane so arranged that the orifices are valvular in nature.

When the urethra is opened longitudinally it can be studied thoroughly. The lining membrane is found to be thrown into longitudinal folds which are close together at the meatus but radiate outward from one another as the urethra widens. The number of folds seen is variable but is usually five. In the region of the meatus these folds are united by a number of transverse ridges thereby forming numerous crypts or depressions into which open the large urethral glands.

The peculiarly rich vascular supply which the urethra possesses is contributed to by the internal pudendal, the inferior vesical and the vaginal arteries. The plexus of Santorini above and the plexus of veins surrounding the base of the clitoris below lie in close relationship with the urethra. Together with their communications they constitute an investment of venous spaces throughout the greater part of the length of the canal. The lymphatics drain into the inguinal and pelvic nodes.

The nerves are derived from the hypogastric plexus of the sympathetic and from the sacropudendal plexus.

Histology The histologic characteristics of the female urethra are well described by Maximow and Bloom, by Smith and by Gray.

The urethra consists of three coats (1) mucous (2) submucous and (3) muscular.

1. The mucous coat is pale; it is continuous externally with that of the vulva and internally with that of the bladder and, as mentioned previously, is thrown into folds. The epithe-

Abstract of thesis submitted by Dr. Palmer to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M. S. in Urology. From the Department of Urology, Mayo Foundation, and the Sections on Urology and Surgical Pathology, Mayo Clinic.

lium varies considerably in different individuals near the bladder it is usually transitional and the remainder of the urethra is lined mainly by stratified squamous epithelium with areas of stratified columnar or pseudostratified epithelium.

2 The submucous coat is very vascular capillaries and large blood spaces abounding. Some of these are located close to the epithelium and in some cases encroach on the basement membrane. Microscopically the submucous coat is found to be composed of a loose connective tissue with an abundant elastic network which is provided with a highly developed system of venous plexuses and has, therefore a cavernous character like the corpus spongiosum. In this coat the urethral glands are found. Each one has a number of branches which communicate with the surface by a common duct. The glands usually have a distinct lumen but occasionally they appear in section as solid masses or columns of cells. They are found throughout the circumference of the urethra and are not limited to the posterior wall as some authors have stated.

3 The muscular coat part of which is continuous with that of the middle circular layer of the bladder wall extends the whole length of the tube and consists of a nonstriated internal longitudinal layer and a nonstriated outer circular layer. The involuntary sphincter of the urethra or bladder is formed by additional muscle fibers which partly surround the posterior portion of the urethra at the internal orifice. Between the layers of the triangular ligament or urogenital diaphragm the canal is surrounded by a layer of superficial striated, voluntary muscle fibers the compressor urethrae or sphincter urogenitalis.

Etiology Since Sharp's original article in 1750 in which urethral caruncle was mentioned many hypotheses have been offered to explain the causation of this condition. No one hypothesis or group of hypotheses has offered a satisfactory explanation therefore most of them will be mentioned in this paper.

Gregoire gave the following explanation based on the embryologic development of the urethra. The meatus and urethra are formed from different anlagen as are the anus and rectum and the hymen and vagina. The corpora

spongiosa form a ring around the orifice of the urethra as well as the vagina. In the process of embryologic development this ring becomes fibrous in the greater percentage but persists in others (Pozzi).

Répiton Préneuf theorized that the various causes of congestion in the female genital apparatus are contributing factors to caruncle formation. Simpson stated that caruncles resemble internal hemorrhoids." Richet and Hutchinson agreed with this and felt that their origin is similar. Goodell thought very much along the same line. He stated that congestion of the urethral plexus of veins as from overdistention of the bladder pressure of the gravid or displaced uterus or like causes is largely responsible the condition resembling hemorrhoids in its origin. In Rose's opinion caruncles are associated with urethroecles which have a direct bearing on their etiology.

Ferner based the causation of urethral caruncle on ruptured cysts of Skene's ducts. He brought out the point that caruncles practically always occur on the lower margin of the urethral meatus just where Skene's ducts open. Carter stated that rupture of retention cysts of Skene's ducts is a causative factor. Olcott also expressed the belief that Skene's glands play a major part in the formation of urethral caruncles.

Gutierrez discussed infection and chronic inflammation—in the form of leucorrhea, pads used during menstruation erosions traumatism incidental to coitus and childbirth and lack of proper local hygiene—as the chief causes of urethral caruncle. According to Gregoire the retention of droplets of urine in the urethral canal as well as of normal or abnormal secretions is a probable source of chronic urethral irritation. Olcott emphasized childbirth as a cause on the basis of its relationship to infection. Crenshaw stated that from his study only one definite conclusion as to causation could be drawn. This is that urethral caruncles seem to be secondary to a chronic irritation or ulceration of the urethral mucosa. Much emphasis was placed by early writers on gonorrhea as the causative factor.

McKim Smith and Rush stated that the cause of urethral caruncle has never been def

intely proved. They attempted to correlate the pathologic with the clinical findings with out much success. They drew the following conclusions from their 202 case studies:

- 1 Vaginal discharge specific or otherwise, and sanitation can be eliminated as having little or no bearing on the direct causation of caruncles.

- 2 Some caruncles were found to be the direct result of trauma.

- 3 Intraurethral caruncles frequently were found behind tight urethral meatuses.

Novak (31) offered the following explanation:

- 1 The caruncle develops from an ectropion of the posturethral wall and is caused by post menopausal shrinkage of the vaginal tissue.

- 2 All the further changes of the everted mucosa are secondary and are caused by the altered environmental conditions.

- 3 There is no relationship to former inflammation of the urethra or the bladder.

Symptomatology. There are few lesions of the entire body which have had so many terms used to describe them. This is based on the symptoms which are out of all proportion to the size of the lesion.

One of the most common symptoms is severe pain which has been described as 'scalding', 'stabbing', 'shooting', 'cutting', and 'burning'. It has been variously described as being referred to genital organs, hypogastrium, perineum, kidneys, rectum, bladder, lumbosacroiliac region and soles and heels of feet. The pain is said to be produced by micturition, sitting, walking, coitus, touch, menstruation, and friction from clothing, napkins, and so forth. Levant and Gutierrez stated that the pain is occasionally so great that the patient puts micturition off until the urge becomes unbearable leading to dribbling and incontinence. Occasionally the discomfort is so great that it leads to neurasthenia, loss of weight, insomnia, despondency, melancholia, and other mental disturbances. On the other hand some caruncles are painless.

Another prominent symptom of the urethral caruncle is bleeding. The blood is usually seen at the beginning or end of urination following coitus, friction from clothes or pads following trauma and on toilet tissue. It is usually spotty

—that is, there are only a few drops at a time—but occasionally it may be so profuse that the patient thinks she is menstruating irregularly. The first noticeable finding may be a small tumor mass and this may be the only symptom which brings the patient to the physician. Other symptoms are division of the urinary stream, urinary frequency, nocturia, and pruritus. Any one or all of the foregoing symptoms may be present. The duration of these symptoms is very variable for example in Walther's series they varied anywhere from 48 hours to 20 years.

Clinical picture and classification. This lesion occurs only in the female urethra. It is found almost exclusively between the ages of 20 and 60 years although rarely it has been reported in children. Gutierrez reported that 33 per cent of his series of 27 patients were multiparas between 50 and 60 years of age. Walther reported 65 cases in which the patients were between the ages of 23 and 84 years and only 1 patient was unmarried.

The gross appearance of urethral caruncle has been described as vividly as the symptoms. Herman in an excellent clinical lecture in 1892 on urethral caruncle described it as a bright red growth like a miniature "cock's comb" or like a very small raspberry springing from the lower margin of the meatus urinarius. It has since been variously described as a small pink or red growth with an irregular surface and vascular consistency' by Walther, a small benign polypoid growth by McKim, Smith and Rush, a small, red pedunculated or sessile vascular tumor' by Stevens and others.

The size may vary from that of a pinhead to that of a walnut but the caruncle is usually the size of a pea. It is usually single but may be multiple.

Urethral caruncles may be classified according to location, gross appearance and microscopic appearance. Gutierrez divided them into three topographic types: (1) those external to the meatus, (2) those internal to the meatus, and (3) mixed those partly within and partly outside of the meatus. Stevens classified them as sessile or pedunculated in appearance. Novak (30) stated that there are three chief types based on the histologic struc-

ture the granulomatous variety made up of granulation tissue the papillomatous variety which has the general structure of other papillomas with a lobulated treelike pattern and the angiomatous or telangiectatic variety which differs from the second type only in the richness of the stromal blood vessels.

Differential diagnosis The term urethral caruncle has become a clinical wastebasket into which most lesions of the urethra are placed. There are almost as many terms for describing urethral caruncles as there are articles on the subject. There has been a tendency for physicians to remove urethral growths as an office procedure and simply call them caruncles and forego any pathologic study. This has led in many cases to what is called a caruncle becoming malignant, because at a later date a biopsy revealed "carcinomatous changes." To be certain of the diagnosis microscopic examination of the tissue is imperative.

There are certain lesions of the urethra from which caruncles must be differentiated.

1. Urethral polyp is usually multiple and lies well up in the urethra. It is cystic, being filled with watery fluid.

2. Urethral papilloma is a definitely benign pluriglandular growth which may arise from any portion of the urethra.

3. Urethral prolapse—that is prolapse of the urethral mucous membrane—is a relatively common condition and is often termed "urethral caruncle." (This condition is included to make the differential diagnosis complete as presented by some authors, even though as will be shown our conclusions are not in agreement.) Urethral prolapse as a rule involves the entire circumference of the external urethral orifice. The tissue is pink to red, usually smooth and points from the urethra. It may be sensitive but not as much so as the majority of urethral caruncles and bleeding is not a common complaint. According to Ferrier actual shortening of the urethra may be apparent on endoscopy. This condition has been treated on innumerable occasions for urethral caruncle and when greater prolapse occurred after operation it was attributed to recurrence of urethral caruncle.

4. Urethral varicoities are supposedly blu-

ish of elastic consistency and readily reduced under compression.

5. Penurethral abscess as well as abscess of Skene's glands may strongly suggest a caruncle. The location in some cases may be almost identical and a tumor mass may be demonstrable with the symptom of marked tenderness. This lesion is definitely of an inflammatory character presenting a purulent discharge, increased heat, swelling and tenderness. It does not present the raspberry appearance so characteristic of the urethral caruncle.

6. Urethral carcinoma may be indistinguishable grossly from urethral caruncle in the early stages; that is, definite diagnosis will depend on microscopic examination. Statistically one is safer to call a lesion of the urethra caruncle because primary carcinoma is infrequent, whereas caruncle is relatively common.

Walther emphasized the fact that primary carcinoma of the urethra is not as rare as most of us think. The age incidence of carcinoma of the urethra is the same as that of urethral caruncle. We must remember that these lesions can and do coexist and that urethral caruncles are not necessarily precancerous lesions. All of the symptoms which characterize the urethral caruncle may be present in a malignant lesion of the urethra. From this it is evident that the final differential diagnosis is left with the pathologist.

7. Urethral condyloma has to be included because it is seen and occasionally is confused with urethral caruncle. It has a warty and fungous appearance with a smooth skinlike surface. These lesions are usually multiple and are painless. The history may be of definite help in the diagnosis.

8. Urethral diverticula and urethroceles can be definitely identified and differentiated by urethroscopy.

Histopathology Urethral caruncle is a clinical rather than a pathologic term. However the condition is by no means rare and therefore constitutes a rather common diagnosis for the pathologist. The histologic structure is not constant a fact which explains the diversity of pathologic terms used to designate urethral caruncles as papillary angioma, vascular polyp, capillary angioma, urethral hemor-

rroids adenoma, granuloma and others. The marked vascularity and inflammatory reaction are most commonly noted and mentioned. The controversy as to whether the urethral caruncle is always benign or potentially malignant still exists.

According to Bell the urethral caruncle is a vascular growth of the meatus and may be either pedunculated or on a broad sessile base. It is a chronic inflammatory lesion composed chiefly of dilated vessels and plasma cells. The surface is covered by stratified epithelium and glands are present in the growth. It may be mistaken for carcinoma. Caruncle is a fairly common lesion but carcinoma in this situation is very rare.

Boyd agreed essentially with the foregoing as did Karsner.

Foot described the caruncle as taking one of two forms: it may be granulomatous and belong to the category of chronic inflammations or it may be adenomatous and constitute a small adenoma in which case it is a neoplasm. The granulomatous type is a loosely knit mass of almost telangiectatic granulation tissue containing many leucocytes of the type that usually responds to chronic inflammation. The epithelial type may be adenomatous or it may take a papillomatous form and resemble an exaggerated leucoplakia or verruca.

Olcott stated that in 5 of his 23 reported cases epithelial infolding was found to a notable degree. This aroused suspicion that the growth was not entirely benign. The absence of definite invasion of subjacent structures, uniformity as regards size and appearance of epithelial cells and the fact that mostly they were properly oriented were all features which should dispose of the suspicions.

Fernier, Levant, Gutierrez, Carter and Meaker agreed with what has been quoted here. Quigley reported that of his 25 cases only 2 presented evidence of malignancy. McKim, Smith and Rush reported 202 cases without evidence of malignancy. Walther emphasized how imperative histologic study of urethral caruncles is in order to exclude urethral carcinoma which he insisted is by no means rare.

Auer identified the urethral caruncle as the predisposing factor in some of his cases of

urethral carcinoma. Menville and Counsellor reported a case in which a urethral malignant lesion was preceded 14 years earlier by a peculiar type of urethral caruncle.

Everett agreed with Bell that urethral caruncle may suggest carcinoma but explained that on more careful examination the uniformity of cell structure and lack of nuclear activity leave little doubt as to its benign nature.

Friedman and Ash also agreed as to the benign nature of the caruncle.

Treatment. It is important to realize that some caruncles respond to any treatment regardless of whether it is conservative or radical. Therefore for a true evaluation of treatment numerous patients should be treated and followed up. The method of treatment has varied little since 1857 as revealed by the following quotation from Scudder's *Diseases of Women*:

No means that may be made use of will have the least effect, until the tumor is removed; this may be done by ligature, caustic, the knife or scissors. Whatever means is adopted for removal of the tumor, without the base of it is destroyed by caustic, it will rapidly reappear as soon then as the tumor is removed; whether by the ligature or scissors its base should be destroyed either by the application of nitric acid or a solution of the chloride of zinc carefully shielding the adjacent parts from injury. This should be repeated, at intervals until the disposition to reproduction has entirely ceased.

The methods of treatment presented in the literature will be summarized in this paper:

I. Conservative treatment

- a. Topical application of caustics such as silver nitrate or phenol, or soothing salves
- b. Radium and roentgen therapy

II. Radical treatment

- a. Simple fulguration
- b. Simple excision
- c. Removal with an electrosurgical knife or electric cutting loop or destruction with an electric needle
- d. Urethroplasty

III. Combination of conservative and radical methods

- a. Simple excision and cautery
 - b. Excision and radium or roentgen therapy
- Conservative treatment. a. Topical application of caustics has been used for a long time as evidenced by the foregoing quotation. Such medications as silver nitrate, phenol, or acid nitrate of mercury (liquor hydrargyri nitratis

acidus) are applied directly to the caruncle on several different occasions. A relative degree of symptomatic relief has been derived from such treatment, which is palliative in nature as pointed out by Meaker. Further or future treatment is based on recurrence of symptoms or recurrence of the tumor. Soothing salves and ointments have afforded relief in some cases.

h Radium or roentgen therapy or the two together have many champions. Meaker stated that radium therapy has many successes to its credit but emphasized that burns should be avoided by the use of protective screens made of silver brass, and rubber. He stated that a small dosage of radium such as 25 to 30 milligrams applied for 2 to 6 hours according to the size of the tumor is adequate. Loucks advised the same.

Quigley reported that radium therapy had been used in 25 cases with 1 to 16 year cures and that this is the specific treatment for urethral caruncles.

Radical treatment. Most authorities agree that simple fulguration—that is, destruction of the caruncle by the use of the electric current—accomplishes little more than the local application of caustics because it is superficial in extent and thereby encourages recurrence. Levant, however, advocated the monopolar type of current for fulguration which he used if the caruncle was telangiectatic and for desiccation if the lesion was papillomatous or granulomatous. He stated that this method has the advantages that it requires only a short time and that there is no possibility of hemorrhage, no possibility of infection, no scar tissue, freedom from postoperative symptoms, rapid relief, and no need of hospitalization.

Ballinger and Elder used the d'Arsonval high frequency current until all of the red growth was whitened.

b Simple excision of the caruncles with the scalpel or scissors has led to a high incidence of recurrence and has been abandoned as a complete procedure in itself.

c Excision with an electrosurgical knife or electric cutting loop or electric needle is advocated by some. Gutierrez advised the removal of caruncles by electrosurgical resection, cutting and coagulating step by step. He used the following plan: procaine hydrochloride is

injected at four points around the lesion; the tumor is removed with an electric knife; coagulation of the wound is carried out with the electric needle for hemostasis. No hospitalization is necessary.

Walther used a similar procedure which he described as follows: overdilatation of the urethra with a Kelly cone dilator or meatotomy is carried out; a traction suture is placed through the base of the tumor; the electric cautery is brought firmly in contact with the base of the lesion; bleeding is controlled by a coagulating current.

Stevens advocated a similar procedure with close follow up and dilatation of the urethra at intervals to prevent formation of stricture.

d Urethroplasty is the method of treatment accepted by many surgeons. All of the procedures and modifications will not be described. Deming described a well rounded procedure. He emphasized that the roots and ramifications of the tumor have to be destroyed to prevent recurrence. He advocated the following routine with the patient under general anesthesia: cuff excision is performed—that is, an incision is made through the mucous membrane around the external meatus; the mucous membrane of the urethra is then separated from the muscular layer for a sufficient distance beyond the tumor; a dorsal slit is made; a suture is placed in the dorsal region and the dissected mucosa is removed; the remaining urethral mucosal edge is sutured to the vaginal mucous membrane. Urethral catheterization is unnecessary. Deming reported complete relief by this method in 8 cases for periods ranging from 14 to 41 months.

Dodson advocated the foregoing procedure for the sessile type of caruncle.

Combination of conservative and radical methods. **a** Simple excision plus caustic or cautery is one such combination. Kickham used a semicircular incision around the caruncle wide enough to include it and deep enough to include the full thickness of the mucous membrane. The caruncle is then excised and the base coagulated with a fine tip cautery. No sutures are necessary.

The Crenshaw method of treatment is carried out as follows (also described by Bumpus and associates):

1 The patient is placed in the lithotomy position and the parts are thoroughly cleansed with soap and water. A swab of cotton on a toothpick saturated in 10 per cent solution of cocaine and lubricated with a soluble lubricant is inserted into the urethra and left for 10 minutes.

2 The labia are separated by an assistant. On examination the caruncle is found to consist either of a single tag on the posterior wall or of posterior or lateral masses. Each tag is picked up with a small Graefe fixation forceps and clamped off in the long axis of the urethra with a special clamp which has a broad blade and a narrow crushing edge. Care is taken to include in the bite all of the caruncle and none of the submucosal structure of the urethra.

3 The growth is cut off close to the upper surface of the clamp; the crushing of the pedicle prevents all bleeding and makes an accurate removal possible. *The specimen is saved for microscopic study.*

4 The cut surface is thoroughly seared with acid nitrate of mercury solution applied with a wooden applicator. An excess of the acid to run over the blades of the clamp and cauterize other areas of the urethral mucosa is cautiously avoided.

Crenshaw reported that in 118 cases there were only four recurrences.

According to Fernier the Crenshaw method as described in the preceding paragraphs is very satisfactory for all but the broadly sessile type. As a modification of this method he advised that if the tumor is sessile it be held with more than one fixation forceps in order to draw it all into the clamp and further in order to avoid the uncertain control of the acid caustic that one use a small electrocautery such as is used by nose and throat surgeons the cut edge being seared exactly as in the clamp and cautery operation for rectal hemorrhoids. He advocated the use of infiltration anesthesia.

Ferret advocated similar treatment but always warned the patient about the great tendency of urethral caruncles to recur.

b Excision and radium or roentgen therapy is another combination of conservative and radical treatment. Walther and Willoughby advised that at one use the radiocutting loop to

remove the caruncle and then follow up this procedure with radium or roentgen therapy.

HISTOPATHOLOGIC AND CLINICAL STUDY OF 120 CASES FROM THE MAYO CLINIC

One hundred and twenty cases of urethral caruncle were taken at random; those in which suitable gross specimens were available being given preference. Multiple sections were made from each specimen and stained with hematoxylin and eosin stain for microscopic study. The case records were studied; special attention being given to genitourinary symptoms and findings, treatment and revisits. Follow up letters were written to all patients requesting information as to their general health, symptoms referable to the genitourinary tract and further treatment for previous trouble with the urethra. The microscopic sections were studied and an attempt was made to correlate these findings with the clinical symptoms, rate of recurrence and age incidence.

The microscopic study included a thorough examination of the surface epithelium, the vascular reaction and the cellular structure. The surface epithelium was found to be of the stratified squamous type in the majority of cases. However, transitional epithelium was present in some. Ulceration of the epithelial covering was most evident in the cases of chronic caruncle and in those in which there had been previous treatment with caustics and so forth. Small islands of surface epithelium were found throughout the sections owing to the normal infolding of the urethral mucosa as described in the first part of this paper. The vascularity of the female urethra as described previously is abundant. The vascular reaction in these cases varied from simple dilatation to extravasation and actual thrombosis. This accounts for the red angry appearance of this lesion which is present in almost every patient. The uniformity of cell structure and lack of nuclear activity is evident (Figs. 1 through 4) and leaves little doubt as to the benign nature of urethral caruncles. The epithelial inclusions and urethral glands were studied closely and a few of the typical sections are included in this paper. The cell structure of the base of these lesions did not reveal the so-called roots or ramifications which have been described. In all

Fig. 1 Regional prolapse showing squamous epithelial covering epithelial cell nests, dilated crypts, many lymphocytes (hematoxylin-eosin stain $\times 55$)

Fig. 2 Photomicrograph of section of caruncle showing glandular element and epithelial nest (hematoxylin-eosin $\times 50$)

of the cases the initial change appeared to be a varying degree of prolapse of the urethral mucosa. This was regional in most instances but was circumferential in others.

Of the 120 cases studied 17 were asymptomatic. The microscopic picture in these cases was found to be the same as in the other 103 cases. The clinical picture was compared with the pathologic picture and no correlation was found. The cases with the most marked symptoms did not necessarily show the most marked pathologic changes. Only minimal changes were evident in some of the cases with severe symptoms.

The pedunculated appearance of some caruncles was explained on the basis of regional prolapse encouraged by the crypts and infoldings of the urethral mucosa. This appearance was further accentuated when irritation due to clothing pads and so forth took place leading to vascular congestion.

From the material studied for the preparation of this paper it is our impression that urethral caruncles are due to several factors. Among these are the anatomic structure of the female urethra which encourages regional as well as circumscribed prolapse; the anatomic location of the urethral meatus, resulting in almost constant exposure to trauma and irritation; and the histologic structure which encourages marked inflammation and congestion as well as increased sensitivity. For these reasons the caruncle may be symptomatic or

asymptomatic; be localized or circumscribed and occur in young as well as old people.

The symptoms of the urethral caruncle may vary from none at all to those of extreme severity. This wide variation cannot be explained on the basis of the gross or microscopic appearance. In this series of cases the signs or symptoms complained of most frequently were pain while sitting, walking during intercourse and so forth; smarting on urination; bleeding from the genital region; tumor mass in genital region; and frequency of urination. The patients complained of any one or all of these symptoms. Several of the patients had no symptoms, the caruncle being discovered on routine examination of the genital region. The size and location of the caruncle had no bearing on the severity of the symptoms. Their duration varied from 10 days to 17 years.

In our series the greatest number of urethral caruncles was encountered between the ages of 40 and 70 years. However, the age range extended from 6 to 88 years; the postmenopausal and multipara accounting for the majority. Of the premenopausal patients 65 per cent had children; of the postmenopausal patients 54 per cent had children. The age of the patient had nothing to do with the severity of the symptoms. As shown in the review of the literature much emphasis has been placed on the age and marital history as etiologic factors. We believe that these are contributing factors and not basically etiologic.

Fig. 3 Section of circumferential prolapse showing same findings as Figure 2 (hematoxylin and eosin $\times 30$)

The different types as described in the literature were seen in this series but regardless of the classification used the basis is still the same—varying degrees of urethral prolapse and irritative reaction. By having so many different classifications one is complicating the picture and encouraging continued confusion. Urethral caruncle and urethral prolapse should be included under the same major heading—urethral prolapse. We are not advocating the discontinuance of use of the term ‘urethral caruncle’ for this term has a definite place in medical literature through its long usage. It could be applied to that group of urethral prolapses which is localized, whether sessile or pedunculated, in contradistinction to the circumscribed or circumferential type of prolapse.

It is evident that the most important differential diagnostic point is obtained by microscopic study of the pathologic specimens. This fact cannot be overemphasized for the ultimate diagnosis depends on this alone. One should not forget that the urethral caruncle and malignant lesions of the urethra can and do coexist.

Treatment. What is the correct treatment for urethral caruncle? This question cannot be answered in this paper and the current literature helps very little. The more one reads the more confused one becomes because there are so many methods and modifications offered. No one treatment is acceptable or applicable in all cases. The incidence of recurrence is high

Fig. 4. Region of thrombosis in a caruncle (hematoxylin and eosin $\times 30$)

if the patients are followed long and closely enough. Classic is Ferner's statement that few lesions of such distressing symptoms have been treated so unsurgically by surgeons.

In this series of 120 cases nearly two-thirds of the patients who answered follow up letters had recurrences of the caruncle regardless of the method used. The number of recurrences varied from 1 to 9. With this high rate of recurrence the patient should be warned that recurrence is extremely likely and that further treatment may be necessary. The main purpose of the treatment offered is symptomatic relief. This should be secured by the simplest and most suitable treatment depending on the nature of the lesion. The treatment should be carried out as an office procedure if possible; a specimen should be preserved for pathologic study. Stricture formation should be made unlikely by following treatment with periodic urethral dilatation and the treatment should be of such a nature that it can be repeated again and again if the lesion does recur without danger of complication.

The objection to the more radical procedures such as urethroplasty is that if they are not performed by a competent surgeon the urethra may be so shortened at the initial or subsequent operation as to result in urinary incontinence. This is encountered most commonly in the treatment of the circumferential type of prolapse where the urethra is actually shortened or the urethral orifices pulled down into the urethra.

Most of the various methods of treatment were described in the first part of this paper. This was done because we feel that all of them may have a place in the treatment of urethral caruncle. No one type will successfully care for all of the various degrees of prolapse each may have its own place and indications. We feel that complete removal is advisable but do not believe that so much emphasis should be placed on destruction of the so-called roots of the caruncle.

CONCLUSIONS

On the basis of a complete review of the literature and review of 120 cases, including follow up of patients and study of microscopic sections of pathologic specimens the following conclusions are drawn:

1 The anatomic and histologic structure of the female urethra encourages regional or circumscribed prolapse. The prolapse may be internal or external to the urethral meatus.

2 The varying degrees of trauma, irritation and so forth to which this prolapsed mucosa is subjected give rise to varied microscopic pictures.

3 Examination of cross sections through the urethral glands and mucosal infoldings has led to the misdiagnosis of neoplasm or precancerous lesion. Urethral caruncle is definitely a benign lesion but may coexist with carcinoma of the urethra.

4 The treatment offered is only palliative and rarely curative. The incidence of recurrence is high and further treatment is often required.

5 Regional or circumscribed urethral mucosal prolapse or both would be the only hypothesis which could explain the occurrence of urethral caruncle in all ages and the varied symptomatic pictures, ranging from no symptoms to most severe symptoms.

A CRITIQUE OF THE McVAY OPERATION FOR INGUINAL HERNIA

THE continued search for improved methods for the repair of inguinal hernia is a laudable effort. New techniques should be critically investigated and if they appear to be logically conceived should be given adequate trial. Many innovations will fall by the wayside. A recent suggestion has been the reintroduction by McVay of the utilization of Cooper's ligament in inguinal herniorrhaphy. This method has been enthusiastically received in a number of clinics and excellent results are reported with it. However, there are certain fallacies apparent in the approach to this method which should receive mention.

On the basis of an excellent study of the inguinofemoral anatomy conducted in conjunction with Dr. Anson at Northwestern University, McVay¹ concluded that the 'funda-

mental error" in current methods of inguinal herniorrhaphy is the utilization of the inguinal ligament as the bastion to which the muscles and fascia of the abdominal wall are sutured. He correctly pointed out that, instead of being a fixed structure as is usually conceived, the inguinal ligament is mobile, being firmly anchored only at its two extremities. During the remainder of its course it is attached to the fascia lata of the thigh by only the thin investing fascia of the external oblique. He found further that the transversalis fascia instead of inserting into the inguinal ligament as is usually described is only loosely connected with that structure and actually inserts into the superior pubic (Cooper's) ligament. On the basis of these findings he expressed the conviction that the almost universal utilization of the inguinal ligament is a cardinal error in herniorrhaphy, and his recommendation was that the Cooper's ligament be used in its stead.

There are several objections to this point of view. To consider this the fundamental error in inguinal herniorrhaphy would imply that operations fail because of lack of fixity of the structure to which the abdominal strata are sutured. Were this so, the recurrences thereby brought about would be due to the inguinal ligament being drawn upward, with resultant defect below it and recurrence in the femoral region. While this type of recurrence may occur, it is certainly very rare. As all descriptions of recurrent hernias testify, the overwhelming majority of recurrences take place above the inguinal ligament, at the site of the original defect. This being so, it is difficult to see how failure to utilize a firmer support could obviate these failures.

McVAY, C. B., and ANSON, B. J. *Surg. Gyn. Obst.* 1948, 74: 747-750.

It is certainly true that the transversalis fascia inserts into the superior pubic ligament and that its attachment to the inguinal ligament is merely one of contiguity through the agency of the thin investing fascia of the transversus abdominis muscle and aponeurosis. Nevertheless any suture placed in the inguinal ligament for the purpose of uniting the transversalis fascia to it must of necessity include the distal portions of the transversalis fascia namely those which extend from the inguinal to the superior pubic ligaments. Continuity of this aponeurotic layer is therefore restored by such sutures.

From a technical point of view there are further objections to the Cooper's ligament technique. The operation is technically more difficult than one those utilizing the inguinal ligament and the possibilities of injury to the femoral vein are vastly greater. While a surgeon of McVay's technical ability and extraordinary familiarity with the anatomical structures involved can unquestionably perform this operation with complete security the same cannot be said of surgeons generally who are charged with the repair of inguinal hernias. Those who have attempted to utilize the superior pubic ligament in the repair of inguinal or femoral hernias are aware of the greater difficulties of exposure. Drawings made from cadaver material in no way portray the problem experienced at the operating table by the bulging and protrusion of the preperitoneal fatty tissue which makes visualization of the superior pubic ramus extremely difficult. More important is the proximity of the femoral vein so that direct trauma and secondary thrombosis must be expected in a much larger incidence than occur with inguinal ligament herniorrhaphies.

The femoral vessels interpose another difficulty. While it is true that the medial portion of the inguinal canal can be closed by

suture of the transversalis fascia with or without internal oblique muscle to Cooper's ligament the lateral portion of the canal cannot be so obliterated because of the presence of femoral vessels crossing the superior pubic ramus. This is the portion of the canal involved in indirect hernias the most frequent of all hernial types. In order to close this portion of the canal Harkins² who has enthusiastically endorsed the McVay method sutures the lateral portion of his fascias to the inguinal ligament. This step-like procedure does not lend itself to accurate closure and the femoral vein itself forms part of the wall of the canal. McVay however uses a somewhat different method. He carefully elevates the inguinal ligament so that the suture line incorporates only the anterior layer of the femoral sheath.³

One further theoretical consideration suggests itself. Any operation which is predicated upon the need of a firm and unyielding bastion to resist the pull of muscular structures must be wrong in its conception. If the sutures themselves are strong enough to resist this muscular pull they will then cut through by the process of progressive ischemic necrosis of the tissues which are subjected to pressure against the suture material. As a fundamental requirement therefore in the surgical approach to any hernial repair the technique must be planned to avoid tension and pull. Otherwise the operation itself is faulty in its philosophy and no amount of strength of suture material or anchoring structure will compensate for what is a fundamental fallacy.

The criticisms detailed above do not in any way deny the correctness of McVay's anatomical observations, nor do they question the excellent results which have been obtained by the Cooper ligament technique. Furthermore

HARKINS, H. N. and SCULLO, R. N. Arch. Surg. 9:17, 1951.
669-709
McVAY, C. B. Personal communication.

the rationale of using the superior pubic ligament in the repair of femoral hernias is obvious. They do however, strongly doubt the assumption that lack of fixity of the inguinal ligament is the fundamental error in current operative techniques for inguinal hernia. And while results obtained may be as good as have been reported it remains to be shown that equally favorable results could not have been secured with the utilization of the more accessible inguinal ligament. Whatever improvement in results may be claimed for the method must be balanced against the added difficulties and hazards which the McVay technique entails. Approached from this point of view it appears scarcely credible that superior pubic ligament will replace the inguinal ligament in the routine repair of inguinal hernias.

THE DIAMOND JUBILEE OF PROFESSIONAL NURSING

LINDA RICHARDS America's first trained nurse graduated in 1873 the year in which the Nightingale system of nursing education was established in three schools of nursing associated with hospitals in New York, Boston, and New Haven. The figure of Linda Richards has become symbolic of professional nursing in America. Able and energetic, Miss Richards went to London soon after her graduation to confer with Miss Nightingale and to work in English and Scottish hospitals until she became familiar with the Nightingale principles of nursing education. Miss Richards established no less than ten schools of nursing during her lifetime, nine in the United States and one under missionary auspices in Japan. Her versatility was further demonstrated by her interest in the care of the insane and in the promotion of visiting nursing services.

For two reasons the times were ripe for the development of nursing. First, women were seeking new opportunities outside of the home. Second, the use of anesthesia and the rise of bacteriological science were contributing to the rapid development of surgery. From that point on, nursing and surgery went forward hand in hand with a resultant rapid increase in the number of American hospitals.

The main principles of the so-called Nightingale system of nursing education were:

1. The nursing service of the hospital and the instruction of nursing students should be under the direction of a qualified nurse.

2. The school of nursing should have its own financial resources independent of the hospital which provided the clinical experience.

3. There should be a planned course of instruction making provision for both the preventive and curative aspects of nursing.

4. A suitable residence should be provided for the nursing students.

With one or two notable exceptions, the early American schools were soon absorbed by the hospitals, lost their identity as schools, and became administrative assets of the hospitals. As time went on, it became evident that the demands on American nurses required a broader preparation than that acquired through an apprenticeship in a hospital. Three important studies of nursing and nursing education have been made during the past quarter of a century.

In 1922 the Goldmark study, financed by the Rockefeller Foundation, pointed out the necessity for more extensive preparation for public health nurses. By 1925 there were more than 2,500 schools of nursing in the United States, many of them operated by hospitals of questionable quality. Lack of standards in these schools led to the organization of the Grading Committee, on which the American College of Surgeons had mem-

bership. As a result of the nation-wide study made by this committee and aided fortuitously by the economic depression the number of nursing schools was reduced to about 1,500. Unfortunately the Grading Committee did not publish a list of schools indicating their rank or grade. Therefore neither the prospective student nor the public was able to determine the quality of any particular school. Many nurses earned diplomas from schools of nursing only to find after graduation that the quality of their education made them ineligible for various types of nursing work.

The third study recently published by the Russell Sage Foundation and popularly known

as the Brown Study was financed by the Carnegie Foundation and clearly points to the next stage in the evolution of American nursing.

One of the characteristics of American nursing has been its willingness to submit to critical self-analysis. The Diamond Jubilee of Professional Nursing gives us an opportunity to acquaint the public with the achievements of the nursing profession in America, and more importantly it enables us to secure the interest and understanding of allied professions and the general public in the further adaptation of nursing service to the present and future needs of the American people.

THE SURGEON'S LIBRARY

THE BOOK SHELF

DOCTOR THOMAS WILLIS AND SIR CHRISTOPHER WREN
BARRY J. ANSON, Ph.D. (Med. Sci.) Chicago, Illinois

IN the entire course of the history of medicine there is no more illustrious association of author and artist than that represented by the collaborative effort of Willis and Wren in the preparation of *Cerebri Anatome Nervorumque Descriptio et Usus* (1664).¹ Each eminent in his profession brought to this conjoint endeavor an ability exceeding that of contemporary writers and craftsmen. While their contributions to the treatise might have seemed at the time equal in value to a present day appraisal of worth would, in respect to accuracy, tip the balance in favor of Sir Christopher. His delineations of neural morphology are so faithful to the dissected subjects that they might be of laboratory service today; the interpretive text by Doctor Willis (Fig. 1) on the contrary is a repository for an outmoded concept of bodily activity. The illustrator's path was observed anatomical features. The author's approach to his task was, of necessity, oblique; his thinking was deflected from a straight course among morphological landmarks, by potent doctrinal winds of Graeco-Roman origin. He must translate mystery as he undertook to explicate the uses of the brain. To Doctor Willis this seemed as difficult a task as to paint the soul, of which it is commonly said that it understands all things but its self. To the nature of their diverse accomplishments we shall return after having reviewed certain important biographical facts.

Thomas Willis began his study of medicine at Oxford in 1642. In that year besieged by the armies of Parliament King Charles retired to Oxford, which he proceeded to fortify. Willis, faithful to the King, was a member of the defending

garrison. Among the notable men in Oxford at the time, was William Harvey, the King's favorite physician. Thomas Willis graduated a Bachelor of Medicine in December 1646. In the same year Harvey left the service of the King and returned to London. Thomas Willis remained in Oxford as a practitioner of medicine. With the restoration of Charles II in 1660 Willis' loyalty was rewarded; he was made Sedes Professor of Natural Philosophy.²

In 1645 before the civil war had reached its conclusion a group of scholarly Londoners organized themselves into a society for inquiry into natural philosophy. By their removal to Oxford in 1648 the society became divided; however they were united and chartered in 1662 by the King as the Royal Society of London. Thomas Willis was elected a Fellow of the Society in 1663.

In his scientific endeavors, Thomas Willis was beholden to Richard Lower and Christopher Wren, and he acknowledges the bond of gratitude in his preface to *The Anatomy of the Brain* for the more accurate performing of this work, Willis writes: "I made use of the labours of the most learned physician and highly skillful anatomist, Dr. Richard Lower for my help and company on the edge of whose knife and wit I willingly acknowledge to have been an help for the better searching out both the frame and offices of before hidden bodies. To Christopher Wren, Willis expresses his indebtedness for the delineation of the many figures of the brain and skull (Figs. 2a to 2d).

Richard Lower was a physician of London and author of a treatise on the anatomy of the heart *Tractatus de Corde* published in 1669. Lower knew that the movement of the blood depended upon that of the heart; he described minutely the whorly course of the cardiac fibers, and their of

Contribution No. 400 from the Department of Anatomy, Northwestern University Medical School.
¹Thomas Willis' original account was published in 1664. Later it appeared as part of a volume of eleven treatises. The combined work is the *Prælectiones Physicæ* published in London in 1684. The treatise on the brain (Number VI of the series) is hereinafter mentioned as a source of quoted passages and of figures. It is the fourth in the *Prælectiones* published in London in 1684.

²Notes from Thomas Willis by William Snow Miller. *Bulletin of the Society of Medical History of Chicago* vol. 3, no. 2, Oct. 1923, pp. 215-231.

fice in contraction of the muscular walls he recognized the correlation between ventricular thickness and muscular effort in systolic contraction, he described and figured the venous valves, and accounted for their function. Lower not only elaborated clearly and serviceably upon Harvey's concept of the circulation, but stated that "what ever statements writers before Harvey made about the movement of the blood through the ventricles of the heart are so empty and worthless that they have already spontaneously disappeared into oblivion." As will be seen however it was Richard Lower a teacher and friend, Thomas Willis, who managed to pluck the outworn notion from oblivious fate.

In his early years Christopher Wren (frontispiece) occupied himself chiefly with astronomical and mathematical studies, and with invention. Following the outbreak of the Great Plague, in 1665 he left London, for a visit to Paris.³ At the end of 6 months, in February of the year 1666 he was summoned back to England, to report on the repair of Old St. Paul's. While so engaged he regularly attended the meetings of the Royal Society then mainly engaged in considering how a return of the pest could be averted. In September of the same year came the Great Fire and the City of London was destroyed. With energetic alertness, Wren submitted to the King his design for the rebuilding of the City. In response, his monarch appointed Wren the Surveyor-General a post which he held for almost half a century. In this capacity he became architect for repairing the whole City the Cathedral Church of St. Paul's, all the parochial churches with other public structures. Certain of these assignments were of monumental proportions—the rebuilding of the dome of St. Paul's Cathedral occupying at least part of his attention for forty years. Additionally he is credited with the rebuilding of some fifty two London churches (Fig. 3).

Christopher Wren's early education was mainly scientific. Not only was he a regular attendant at meetings of the Royal Society but also one of its founders and later its President (in 1680). He was a member of Parliament, a shareholder in the Hudson Bay Company during the period of England's territorial expansion, and a public-spirited Londoner who was consulted on all matters connected with the City—unrelentingly assiduous, to his death at ninety-one years of age.

Before Christopher Wren became an architect he was already a scientist of European fame, a

compeer of Harvey and Newton. His genius was displayed not only in the fields of mathematics, astronomy and invention, but also in some departments of medicine. He came to occupy the chair of Astronomy at Gresham College in London at the age of twenty-five three years later he was appointed Savill Professor at Oxford. With the genius of a Leonardo he invented, or proposed plans for a weather-clock, an artificial eye with humoral content, an instrument for writing double new ways of engraving and etching and methods of submarine navigation. He introduced liquids into the blood stream of animals, forecasting similar experimental practice in transfusion and in hypodermic injection. In the field of physiological experimentation there is, curiously no reconciliation between his own observations and the physiological notions held by Willis—as there is none between theirs and the concepts of Harvey and Lower. Despite the fact that they were colleagues and fellow members of the Royal Society their anatomic views seem insulated possessions—individually held, and never reconcilable contributions to an accumulated store.

Sir Christopher Wren's figures of the brain (Figs. 2a to 2d) take their place in a large gallery of neurological illustrations (Figs. 4a to 4f, 5a to 5f).⁴ Predecessor pre-Vesalian, figures are those of Albertus Magnus, Johannes Peyligk, Gregor Reisch, Wendelin Hock, and Johann Dryander; those encountered in the magnificent *Fabrica* of Vesalius, and in the contemporary volumes by Charles Estienne, Constantio Varelio and Bartolomeo Eustachi; in the later treatises by Caspar Bartholin, Johann Vesling, Raymond de Vieussens, Godfried Budloe and Giovanni Domenico Santorini—and all these antecedent to the first editions of textbooks of gross anatomy and neuroanatomy. Wren's drawings are less delicate than those of Santorini, less forceful than the neurological figures in the Vesalian *Fabrica* they are far more attractive than the contemporary illustrations in the *Synopsis* of Vesling, in the *Anatomographia* of Vieussens, and in the *Institutiones* of Bartholin; they are more analytical, though far less statuesque, than the comparable figures in the folio volume of Bidloo.

In order to appreciate fully the degree to which Willis' system is dependent upon the primitive ^{4a} these two plates of illustrations all but figures 2a to 2c and 5a were photographed from the original volumes. In the Archibald Church Library of Northwestern University Medical School. Figures 3a and 4a were copied from the *Opera Omnia Anatomica* of Christopher Wren, published in 1725, which is the 725 revision of Andreas Vesalius' *De Humani Corporis Fabrica Libri Septem*. In the edition of 1725 the figures were reproduced from copper engravings. It will be remembered that the three editions (1543, 1555, 1565) of the *Fabrica* published during the life of Vesalius contain wood-cuts, again used in the German edition (1783) by Lervet.

³Biographical notes from Sir Christopher Wren, Bicentenary Memorial Volume published under the auspices of the Royal Institution of British Architects. Hodder and Stoughton, London, 1923.

writings in the medical sciences, it is necessary to examine more than his accounts of the heart and of the brain. The essential elements are continued in the *Practice of Physick* published in 1684 (Fig 6). Herein the reader is presented with an inclusive picture of medical concepts which are negligibly influenced by William Harvey's account of the nature and the circular movement of the blood. More than a half century after the publication of Harvey's treatise, and fifteen years after the appearance of Richard Lower's tract on the heart, Willis' concept of nervous physiology was still based upon the Galenic notion of vapors and distillates—a system which then was fifteen hundred years old.

Thomas Willis, eschewing the knowledge recorded in the works of Harvey and Lower clings to the ancient doctrine of the spiritus or pneuma perpetuating the traditional belief that the body of man is an anthropomorphous sponge designed to house a leavening breath of celestial origin. Air with its burden of spiritus, was thought to be inhaled and vented through the trachea and the innumerable cutaneous pores the latter openings being described as if they were the peripheral ostia of the blood vessels. Alimentary fuel for the bodily fire was carried by the portal vein to the liver in the liver this nutrient chyle transformed into the natural spirit whose function it was to control nutrition, growth and reproduction. The heart drew this nutritive mixture from the hepatic pulp to its own right chamber wherefrom it was wafted through the interventricular wall—supposedly porous—to attain the left ventricular chamber. Mixed with the inhaled breath, the natural spirit was converted into the vital. The greater part of this vaporous compound was believed to be carried away by the arteries to serve as the source of life and the bodily heat. However a small part of this life-giving spirit was admitted to the complex arterial network at the base of the brain. In this miraculous plexus, termed the *res mirabile* the spiritus was rendered fit to perform the animal functions, that is, to impart sense and to cause motion. In this thrice refined form the spiritus lingered within the brain as the substance of opinion and judgment and the stuff of the human soul.

Doctor Thomas Willis modernized this early philosophic doctrine by bringing to the Galenic notion of pneumatic elaboration that of fermentive inkindling. Willis believed that fermentation is not limited to the formation of yeast, to the souring of vinegar and to other ordinary zymic processes, but that it is an all pervasive chemical phenomenon which accounts as well for the nor-

Fig 1. Portrait of Thomas Willis, Sidley Professor of Natural Philosophy at Oxford.

mal beating of the human blood and for its uncontrolled intensity in fevers. Willis believed that the process of distillation was as essential in bodily metabolism as it was fundamental to the preparation of healing pharmaceuticals. Distillation served as a means of separating volatile materials from substance of more fixed character. In simple form the apparatus consisted of a gourd-shaped cucurbitte a shrouding alembic cemented to the former a stove and a receiver (Fig 7). The substances were macerated and digested in the heated cucurbitte the vapors, condensed in the alembic, were carried away through the beak of the alembic to the receiver.⁶ As will be seen Willis found the counterparts of these distillatory pieces in the human thorax and head. To him, the calvarium together with the subjacent meninges and brain was a kind of alembic, the heart

and its great vessels behaved as the cucurbit and the distilling stove (Fig. 8)

Although he retained the ancient distillery as part of the physiological machinery, Willis, influenced by the then new chemistry, could no longer regard the spiritus as a self-sufficient vapor intermediate between body and soul; he must think of it in association with sulphur, niter and salt. In his system, heavenly spirit became an alloy through fermentive interaction with mundane elements. Regarding the spiritous part of the compound, Willis writes that its constituents are highly subtle, Aethereal Particles of a more Divine Breathing, which our Parent Nature hath hid in this Sublunary World, as it were the Instruments of Life and Soul, of Motion and Sense.

the oblong marrow, the fornic or arched vault, and other processes, may be clearly and distinctly beheld." c. "The brain of a sheep bent back and cut a little open in the places where they stick together near the streaked bodies, that its interior substance may be turned the inside out and unfolded on a plain." d. Represents the oblong marrow taken out of the head of a sheep with the brain cut off and removed, and with the cerebellum and one streaked body cut in two in the middle, and other things chiefly belonging to the medullary trunk."

Being volatile, they are always endeavouring to fly away; consequently lest they should too soon leave their subjects, they are bound sometimes with more thick Particles. Through the process of fermentation, operative within the chambers of the heart and its major vessels, the particles of the four elements, freshly ebullient, like Water boiling over a Fire, the blood is propelled through the vascular channels, not without great Tumult and Turgescency. The degree of admixture makes a chemical hierarchy with the motionless minerals of fixed nature at one end of the scale, and living creatures at the other—the animate things being rich in spirit, as would be requisite for sense and motion.

Willis would extend this concept to account for the final elaboration of animal spirit in the brain. This is the textual and pictorial burden of the *Cerebri Anatome*. Doctor Willis ventures the guess that the Brain with Scull over it, and the appending Nerves, represent the Little Head or Glassie Alembic a Sponge laid upon it, as we use to do for the highly rectifying of the Spirit of Wine. The blood rarefied by the cardiac beat, is carried from 'the Chimney of the Heart' to the

more fit for the performing the offices of motion and sense to this end the substance of the Brain is exceeding full of a Volatile Salt which is of great Virtue for the sharpening and subtilising the spirits.

In the treatise entitled *Of the Accension of the Blood* Thomas Willis discusses particularly the growing hot or inkindling of the Blood (Fig 6) In order that a flame may be inkindled in the heart and continue to burn there is need of a free and undiscontinued access of Air to this end the action of the lungs serves to carry away the vaporous Effluvia, threatening the suffocation of the flame and to supply nitrous food neces-

sarily requisite for the burning Like a flame the life of the blood may require additional ventilation to which end besides the greater breathing places of the Breast innumerable lesser or the Pores of the skin gaping everywhere through the whole Body do send forth Effluvia departing plentifully from the boiling blood If alimentary fuel for the cardiac fire be denied the vigor of the blood is diminished and when the nutriment becomes too thin and watry the fervour of the blood like flame without food uses to be remitted

Recognizing that the flame inkindled in the blood appears not at all, Willis records his belief that it is most thin and burns in the Heart

Fig. 6. The page of Thomas Willis' *Practice of Physick* (684)

and its depending Vessels as it were shut up in Receptacles it does not blaze clearly but perhaps remains in the form of smoke or a vapour or breath even should the blood "openly flame out yet it might be so done that its shining being most thin, may not be perceived by our sight, as in the clear light of the day we cannot behold a glowing red-hot iron, nor shining sparks, nor false fires, nor rotten wood nor many things shining by night."

Willis finds support for his opinion in the fact that some "hot living Creatures send forth certain fire or vaporous blood, when they have put off their inner garments night going to bed under fire or Candle. Similarly it is noticed in burning Fevers caused by immoderate drinking of Wine or strong Waters, that the blood, as the flame of it is very much increased, doth grow extremely hot, even to the degree that some bodies, they have seen the burning fire and flame in the eyes; these other wise argue "that the blood is very strong, and also that it penetrates the enclosure of the Brain. Willis himself knew certain ingenious Men of very hot brains, who found that after very plentiful drinking of Wine, he was able in the darkest night to read clearly.

In accounting for the further movement of the heated spiritus, the arteries, veins, venous sinuses of the dura cerebral ventricles, cerebrium, cerebellum and medulla oblongata are all brought logically but erroneously into the traditional physiological scheme each gross anatomical part is employed as if it were a living sieve retort or pipe in a neurological distillery. When it is received from the heart the spiritus finds its loftiest residence in the brain. In this final anatomical station it is fully elaborated, preparatory to carriage by spinal and peripheral portions of the nervous system to the muscles and to the organs of sense.

The large vessels, carotid and vertebral are the major conduits from the heart to the brain either pair of these inclining one towards the other are mutually conjoined. Correspondingly the meninges are stuffed throughout with veins, sent from four bosoms" (the dural sinuses of our description) which ultimately receive the blood from the anastomosis of arteries now termed the *circulus arteriosus Willisii* (Fig. 2a). The veins like promptuaries or store houses framed in several places, are destined to receive the blood "returning from every region and corner of the brain and at length transfer their burden into the jugular veins."

The globous brain is aptly described as being marked externally by chinks, "turning and winding like to the rollings about of the intestines." Upon removal of the cerebral hemispheres there is exposed an internal substance which throughout its extent is chamfered or streaked. In Willis' opinion these markings "were made by nature, as it were passages or channels for the passage and return or going to or from of the spirits out of the cillous body into the oblong marrow and on the contrary (Fig. 2b). That is to say cerebral substance is physiologically important in so far as it is a spongy or a foraminous mass fit to transmit the nervous spirits.

The cerebral mechanism is protected by the bony skull internal to which the hard outer meninx (*dura mater*) serves to restrain and keep within the brain the effluvia of the animal spirits, lest they should too thickly evaporate and thus be dissipated to the great detriment of the body. This heavy meninx is important also in containing capacious cavities ("bosoms" in Willis' terminology) which "like promptuaries or store houses framed in several places, receive the blood returning from every portion of the brain finally transferring their contents to the jugular veins. These sinus-like enlargements are, how ever more than storage depots they too are auxiliary refineries, since while the blood remains

Fig. 7 Ancient distillation. From *Pictorial History of Ancient Pharmacy* by Hermann Peters, translation by Wm. Netter Chicago G. P. Engelhard Co. 1889

collected within them, it seems to be the source of heat, requisite for the distilling forth of the animal spirits as if it were a certain chymical reaction. These bosoms, then, are like a certain distillatory bath, so the other membrane of the dura mater being stretched out about the whole head is like an impervious alembick, which with its covering keeps within the spirituous breaths that they not be immoderately evaporated. In this way by admirable contrivance, heat is engendered in the localized furnaces, and is conserved by dural and osseous insulation.

The interior soft meninx, far thinner than the exterior is covered over throughout with the infoldings of arteries and veins, and so waters all the spaces of the brain and cerebel with unnumerable rivers. Then these arteries and veins meet in anastomoses, in order that the blood to be earned from the heart into divers regions of the brain might be exactly mingled as to its parts and particles, before it come to the place designed. They are multiple in order that 'if by chance one or two should be stoppt, there might easily be found another passage instead of them.'

Thus it is that the meningeal and cerebral vessels which carry the vapors through the whole compass of the head are like distillatory organs. The latter in the process of cephalic circulation

separate the purer and more active particles from the rest, subtilize them and finally insinuate the spiritualized elements into the substance of the brain. The spirituous distillate regardless of what its destination may be, must first be absorbed in this fashion by the brain tissue to that end its whole exterior superficies is made uneven and broken with turnings and windings and rollings about almost like those of the intestines, thus, with a complex pattern of gyri and sulci, it is framed both for the more plentiful reception of the spirituous aliment, and also for the more commodious dispensation of the animal spirits. This nutrient spirit is not only drunk in everywhere in the plain superficies but also through the walls of the sulci, the folds being so disposed in order that the spaces for the receiving the juyce might be enlarged.

These animal spirits, derived from the spirituous liquor are carried into the callous body, as into a spacious field. The corpus callosum (Fig 2c, at K) according to Willis, is the headquarters of the animal faculties, there residing as in a publick emporium or mart from this repository as occasion serves, they are raised up and drawn forth for the uses of every faculty. While at relative leisure, they gently circulate through the corpus callosum and spread to the fornix. In

musings or reveries, the streaked pathways of the fornix are their sheltered lanes along these are engendered our sorrows and sighs, our joys and smiles.

At regular intervals the cerebral tissue becomes surfeited with its spirituous content flowing inwardly it stuffs all the pores and passages of the brain, and so excludes for that time the spirits from wonted tracts and orbs of expansion whereupon sleep, or an eclipse of the animal spirits happens. Conversely, waking returns, when from the liquor unstilled, the more subtil part is exalted into very pure spirits, and at length the more watry being partly resolved into vapours, is exhaled, and partly supped up by the passages entering the substance of the brain.

This discussion of storage introduces the matter of the cerebral ventricles, for which a use is found in the traditional manner.

The presence of the ventricular spaces had brought pacific pleasure to the philosophers of the early Church. Albert Magnus, the learned Dominican depicted them in stylized fashion (Fig 4b) they offered a sheltered nidus for the soul a place for ultimate refinement of a spirit whose source was celestial. By Gregor Reisch, Confessor of Emperor Maximilian I they were compartmentalized to care for the activities of imagination, cogitation, fantasy, memory and the kindred forms of cerebration. In Peyligk's medieval compendium for lay scholars, the ventricles took the traditional form (Fig 4a) to subserve the familiar philosophic function. And although the anatomy of the scalp and cranium was pictured with structural correctness by Dryander the ventricles were superimposed upon the calvarium in stereotyped treatment (Fig 4c). Willis must fit these cavities into his schema since there is nothing met with in Nature that is not destined to some use. But he modifies the inherited system to meet his needs. In Willis' opinion the serous latex which is the vehicle of the spirits, and is introduced together with them into the pores of the brain "after it is grown stale and being attenuated into vapour doth distill forth into this cavern and there at last grows into a watry humor. The humor having served its purpose as a vehicle is then removed by the veins—as if it were a condensation falling into the cucurbitule.

The discussion then passes from the brain to the "spinal marrow. In form it is forked, as it were like the poets Parnassus, like the letter Y (Fig 4d). Because of the relative directness of its course from head to tail and because of the simplicity of its structure the oblong marrow seems to be a broad or high road into which all the ani-

mal spirits perpetually flow from their double fountain to wit the brain and cerebellum, to be derived from thence into all the nervous parts of the whole body. From the cephalic stations the animal spirits are directed either outward towards the nerves, when they exert the locomotive faculty or they look inward towards their fountains, when the acts of sense, or rather the apprehensions of sensible things are performed." Within the oblong marrow "a more large and greatly open path leads straight to the spinal marrow through which the spirits flow forth to the nerves, the executors of spontaneous motion in most members.

The cerebellum possesses a characteristic morphology and is designed "for some works and wholly distinct from the brain." While within the brain imagination, memory discourse, and other more superior acts of the animal function are performed, it is the office of the cerebellum to supply the animal spirits to those nerves by which the involuntary actions (such as cardiac action, respiration, and digestion) are carried out after a constant manner unknown to us, or whether we will or no. And while we may be aware of the movement of spirits in the cerebrum, those which inhabit the cerebellum "perform unperceivedly and silently their works of nature without our knowledge or care." The difference in spirituous behavior is a consequence of observable structural characters (Fig 4b) for whilst the brain is garnished as it were with uncertain meanders and cranking turnings and windings about, the cerebellum is furnished with folds and lappets disposed in an orderly series." Within the cerebellum then "the animal spirits are expanded according to the rule and method naturally impressed on them as it were in a certain artificial machine or clock, not as the same spirits are regimented in the cerebrum where they are continually driven into fluctuations as it were with the winds of passions and cogitations." From the cerebellum the oblong marrow is continued into the utmost recesses of the whole spine or backbone. This medullary prolongation, the spinal marrow "is as it were the common passage or channel of the spirits flowing out of the head into the nerves." They follow the nervous pathways to the muscles, return by them from the organs of sense. The swellings at the brachial and the lumbosacral levels resemble according to Willis, the widenings which occur in a channel where rivulets are received.

Thus Thomas Willis succeeded in utilizing all the gross anatomical eminences, gyrate ridges, arches, vessels and investments found within the cranial cavity in this investigation he was un-

aided by experimentation or staining procedure.⁷ Willis anatomical studies carried him far in the field of gross morphology: he presented the four-fold arterial supply and dural venous reservoirs in the detailed manner now made familiar to all students by our modern encyclopedic textbooks: the chief macroscopic features of the cerebrum, cerebellum, medulla oblongata and spinal cord were accounted for in his treatise. However in zealously attempting to discover a use for each dilated vascular channel, laminated prominence, ventricular space, foramen and medullary rootlet, he was drawn into fallacious physiologic interpretations. Thomas Willis progressed as far in the field of functional interpretation as the ancient, and astonishingly persistent, system of physiology would allow. Thinking only in terms of the transmission or of the temporary warehousing of the spiritus, Doctor Willis sought in each discrete anatomic structure a suitable headquarters for a vaporous distillate. *Distillation gave evidence of the existence of minute tubules, not of the presence of nerve fibers: nuclear bulging indicated a massing of spongy substance, not the grouping of cell bodies. Influenced profoundly by the inherited medical beliefs of his own and of past centuries, Willis assigned a chemical function to the heated blood: the meningeal vessels, the dural shroud, and the cranial vault. They represented parts of a human balneum Mariae. Willis reasoning that whatever refining process was serviceable in the preparation of a medicine must be infinitely more important in the purification of a vapor which is destined to become the soul of man, did not hesitate to put into the cranial cavity the neural counterparts of an apothecary's paraphernalia. The *Cerebre Anatome* therefore bridges the gap between the sixteenth century Vesalian neuroanatomy and that of our own day: with interpretative resourcefulness and ingenious logic it fits new anatomic pieces into a predetermined physiologic pattern.*

It must be remembered that Willis was limited by the power of gross observation: his knowledge was gained solely by dissection. No one had seen the cellular constituents of a nuclear mass, the fibrillar content of a neural tract, the histologic elements of bark and pith of cerebral and cerebellar cortices. Spaces were interpreted as reservoirs to receive, cleanse, store and dispense the spiritus; laminar walls were scribed tracks for the guided

A correct interpretation of cerebral and cerebellar function must wait, of course, on clear demonstration of the tract, even the pioneers of modern neurology presented their discoveries as late as the nineteenth century. In the sixty years between 1819 and 1879, Burdach, Goll, Gowers, Clarke and Flechsig described the tracts, fascicles or columns which bear their names.

Fig. 8. Distillation in Balneum Mariae. a, Copper vessel full of water; b, Gourd-shaped flask, or cucurbit, containing the material to be distilled; c, Door through which a lamp is placed, then closed; d, Oil lamp, with three or four wicks, beneath the vessel; e, Openings through which air enters; f, Two pipes, passing through the water, by which fumes escape. and enchanneled movement of the same eminences were manufactories or places for collection of excrementitious wastes—of dregs removed to sanitize the vital fuel: nerves were pervious branches of a medullary tree—whose porosities were arborescent continuations of larger spaces at the core of the brain.

Similarly Thomas Willis' explication of cardiovascular action is fundamentally Galenic: his notion of arterial content is rooted in Empedoclean and Aristotelian philosophy. Willis adds the chymical phenomenon of admixture. While the spirits are the ethereal particles of a divine breathing sulphur, salt and nitre are of earthly derivation. In the animal body the several kinds of particles, by fermentation break apart: the rarefied part, like Water boiling over a Fire, is carried through the vessels with great tumult and turgency, moved by the vital ferment in the

Chimney of the Heart. In Willis' schema, as in that of the ancient writers, the heart is the important workshop of the blood. Willis adds to the older concepts a description of a mechanism for heating the blood. He believes that it is accom-

REVIEWS OF NEW BOOKS

THE author of the book entitled *Histopathologic Technique*¹ had certain very definite purposes in mind. It was written to give a systematic treatment of recent advances in this field without attempting to be encyclopedic in scope. Many methods that have been included in previous works on this subject have been excluded either because they are obsolete or impractical or because they have been replaced by better methods. He has endeavored to find methods that depend for constancy of results on controllable factors such as time, temperature, bydrogen ion concentration, and concentration of reagents rather than upon the skill of the technician. Most of the methods described are applicable to tissues fixed routinely in formalin rather than in special fixatives. The author has himself made many modifications and improvements of older methods.

The volume is divided into 21 chapters. The first 15 chapters deal with the use of the microscope, the equipment essential to histopathologic technique and the general principles of fixation, decalcification, sectioning and staining. These are followed by 3 chapters dealing with the staining of specific parts of tissues such as nuclei, cytoplasm, enzymes, pigments, cell product (silver, mucin, etc.), fats, and lipid connective tissue parasites and tissue of the nervous system. Chapter 16 describes methods of dealing with hard tissues such as teeth and bone. Chapter 17 describes various special procedures such as vascular injection, corrosion, autoradiography and microneuroanatomy. The final chapter deals with buffers with a description of the principles involved and 5 pages of tables for the making of various buffer solutions.

Of particular importance is the chapter dealing with the formation of enzymes in tissue. Methods are described for alkaline and acid phosphatase, lipase, lactase and diaphenylase. These are among the more recent significant advances in histochemical technique.

[illegible]

References are given for all the methods described and their modifications. The entire volume is well written and anyone who is interested in histologic technique will find it extremely useful.

Opal E. Hulse

IN the strict sense of the word *The Long Ill*⁸ by Betsy Barton is not a novel. No central character nor theme of events nor climactic adventure form the axis of the story. Rather it is a depiction of the routine events and experiences on a ward for men with injuries of the spinal cord in a Veterans' Administration hospital. The passage of a few hours in her story has been sufficient for the author to lay bare with a restrained hand the personal tragedies, frustrations, unfulfilled dreams, and warped philosophies which may be a part of doctors and patients alike.

The story has to do with the mastery of individual fears and conflicts which leads to a happier personal life and a life more useful to others. Woody helped his ward mates by example, but his own cares were resolved only in death. Arthur, the hospital psychologist, was unable to succeed in his own work until he had found the means and strength to heal himself. Henry, unbothered by the usual mental fetters of the paraplegic patient, became truly rehabilitated. Janet, through whom the author speaks autobiographically and therefore knowingly, expresses the long struggle with the emotional adjustment that is necessary before the "outside world" can be risked. For the person of casual interest in the problem of the paraplegic patient this book will do far more toward a clarification of their needs and problems and especially toward an understanding of their feeling of safety in isolation and of their despair and detachment than will any amount of markedly conceived non-fiction on this all too popular subject in current magazines and newspapers.

Fortunately the author has availed the maudlin — an error in treating of her subject. Nor has she shown the injured patient in all clean all moral completely deserving light. She has shown how that a brutally dull group of patients can render all treatment futile by their own attitude of futility. She has indicated what all discerning doctors know, that is that if the patient can be helped by his doctors to realize fully the meaning of his condition and to accept it and to take up his life again on a new but by no means hopeless plane, the greatest hurdle will have been passed. Through Janet the reader can learn why the intelligent patient has difficulties in accepting his new limitations, and all through St. Lawrence's eyes the audience is led but which is to reveal the Doctor's faith.

Charles W. & Peter F. the school don't land
any more.

usually poorly informed persons, including many doctors, should read this book.

Many passages will bear close reading and re-reading. Some of the prose is excellent. And it is excellent because of its sincerity directness, and clarity. Brief passages descriptive of little ward events could have been written only by a person both keen and honest. One may feel that with her second book Miss Barton has quietly reached maturity as a writer. JOHN MARTIN.

THE first edition of *The Hospital Care of Neurological Patients* appeared eight years ago and in that interval it has been popular with internes residents, and nurses who it seems are almost all ways puzzled by it not in actual fear of the problems of neurosurgical care. The present edition is somewhat enlarged, but yet it does not pass the convenient manual size. Certain additions have been made concerning the relations of the house officer to the patient, the attending surgeon and other personnel in his own and other departments. There is added a discussion of the use of the antibiotics, developed since the first edition, and the subjects of intervertebral disc protrusion and prefrontal lobotomy are covered briefly but adequately for the purposes of the book. The organization of the book has been improved. Certain minor errors in grammar and terminology are still present in the second edition. The book is written in easy clear language, and while as the author states, no attempt has been made to lay down hard and fast rules for neurosurgical care (that varying with the policies of the individual surgeon) yet the basic plan of care as outlined serves as a safe guide for the young physician and the interested nurse. JOHN MARTIN.

THE small book *Physical Treatment of Injuries of the Brain and Allied Nervous Disorders* by K. M. Fern represents the honest efforts of the author a physical therapist, to apply her own concept of what is basically essential and effective in physical therapy for the patient with a brain injury. Her theme is "Teach the patient how to do it for himself." She apparently puts little faith in the use of massage, passive exercise, and other standard forms of therapy leading to rehabilitation. So far as the book goes, it shows, by elementary illustrations and English which is almost too simple and informal, some of the steps by which patients can be taught confidence and to carry out co-ordinated movements with their strength which has hitherto been present but misguided. The book gives the impression of being merely a chapter in a larger book on various techniques in physical therapy. There is little that is actually original in it, it is tiresome reading, it does not contain much instruction from page to page.

THE HOSPITAL CARE OF NEUROLOGICAL PATIENTS. By Wallace B. Hamby M.D. F.A.C.S. and ed. Springfield, Ill.: Charles C. Thomas, 1944.

PHYSICAL TREATMENT OF INJURIES OF THE BRAIN AND ALLIED NERVOUS DISORDERS. By K. M. Fern. Baltimore: The Williams & Wilkins Co., 1947.

because of a repetition of method of instruction and it is doubted if it will fill any wanted information for well trained American therapists. JOHN MARTIN.

IN the volume, *Identification of Tumors* by Nathan I. Chandler Foot, a new approach has been used to delineate the pathology of tumors. Before using this text it is essential to read the preface. Here, the author establishes the basis for his different presentation.

There is a specific aim for simplicity. Controversial matter is eliminated. There is a division into two parts: one, the neoplasms of general distribution and the second the neoplasms of special systems and organs. For some reason tumors of the cardiovascular system are considered in part one. There is a section at the end which may be used to systematize the histologic diagnosis of various new growths. There is a chapter on the technical methods of fixation and staining which, to this reviewer is unnecessary.

This organization purveys a set pattern the source the site age and sex, gross appearance, microscopic appearance, differential diagnosis, and prognosis. In most instances, there is a photomicrograph in black and white. In general, emphasis is laid upon the microscopic picture.

The major flaw in this entire volume is the use of heterogeneous classifications for the various systems. They must be those of the author. These classifications are confusing to trained pathologists and must be more so to the persons for whom the book was written. Many contain combinations of clinical and pathologic terms to the detriment of both. The outline of breast tumors is particularly distressing and that of the skin is somewhat obsolete.

It is recommended that when this text is revised the classifications be simplified in conjunction with the purpose as defined in the preface and that the sections on technical methods and the tabulations be discarded. With these changes, and even in this present issue if the factors mentioned are ignored, the book will serve a distinctly useful purpose in acquainting the interested though untrained man in the morphology of human neoplasms.

M. C. WHITLOCK.

TO present in a few paragraphs an adequate appreciation of a volume of 700 pages which represents the results of 3 years of conscientious study of careful experiment, and of wide clinical experience in the care of surgical infections is the formidable task which faces one in reviewing McEneaney's excellent *Treatise on Surgical Infections*. No one familiar with the development of surgical practice during the last quarter of a century but would agree wholeheartedly with Whipple's splendid tribute in the

IDENTIFICATION OF TUMORS. ESSENTIAL GROSS AND MICROSCOPIC PATHOLOGIC FEATURES SYSTEMATICALLY ARRANGED FOR EASIER IDENTIFICATION. By N. Chandler Foot, M.D. Philadelphia, London, Montreal: J. B. Lippincott Co., 1943.

TREATISE ON SURGICAL INFECTIONS. By Frank LeMott McEneaney M.D. New York: Oxford University Press, 1942.

introduction since Lister's time no surgeon has studied so intensively and has made so many original contributions to the subject of the bacteriology of infection and inflammation requiring surgical therapy as has Dr Meloney in the past twenty-five years.

The volume opens with a historical chapter on bacterial activity in its relation to life and an account of the slow awakening of men of medicine to the importance of inflammatory disease and the possibility of treating it by destructive agents. Hospital gangrene in the Civil War is considered at some length with quotations from Jones' *Surgical Memoirs of the War of the Rebellion* that describe cases of rapidly spreading streptococcus infection with chronic undermining ulcer. The two latter conditions illustrated in color in the frontispiece are of especial significance because they continued to baffle surgeons for many years after the Civil War and only in recent years was their true character finally recognized as a result of Meloney's long continued bacteriological and experimental studies. The chapter closes with an appreciation of Pasteur and Lister and of their fundamental contributions to surgical science.

In Chapters II, III and IV "Surgical Infections and their Classifications, Sterile Technique, and Sterilization the author differentiates surgical infections from medical infections and classifies surgical infections by the time and manner of onset and with postoperative infections by the site or body system chiefly involved. Under Sterile Technique the many potential sources of contamination of operative wounds are considered in detail. The larger part of the so-called sterilization is devoted to the problem of effects obtained and of the practical applications of the various methods.

Chapter V by Edwin J. Pulsakion, Antiseptics and Disinfection in Relation to Surgical Infections, includes a concise discussion of the action of many varieties of antiseptics and disinfectants beginning with the surface antiseptics and continuing with the metallic salts, the oxidizing agents, the phenols, and finally the sulfonamides and antibiotics. Through the many antiseptics discussed are not purely bactericidal, but many are bacteriostatic. The picture of the constant evolution and progress that have come with the passing years in this important phase of surgery.

In Chapters VI and VII, Infection in Clean Operating Wounds and Infection in Accidental Wounds, the author discusses on the basis of his personal observations a large number of the im-

portance of adequate masking of careful records of wound healing and postoperative infection of the importance of the type of suture material and its complete sterilization and (in Chapter VII) the results of the studies on the care of wounds and burns made under the direction of the National Research Council during the war years. Though the latter have had wide publicity and evoked much thoughtful discussion many men are still reluctant to accept the thesis that chemotherapeutic agents which are consistently helpful in overcoming spread ing infection and which often produce dramatic results when given by mouth or parenterally do not necessarily prevent or control infection when applied locally in contaminated or infected wounds. The explanation however becomes increasingly clear in the later chapters which deal with bacterial establishment and spread in the human body.

Miss Balbina Johnson, long an able associate in the Bacteriological Research Laboratory at the Presbyterian Hospital, contributes two important chapters, IX and X, "The Bacteria That Produce Surgical Infections" and "Methods for Bacterial Cultivation." The latter is not intended to be a complete manual of bacteriological techniques used and found satisfactory in the study of surgical infections in the Presbyterian Hospital. It has been thought and effort Miss Johnson has brought to her task is evidenced by the fact that Chapter IX is documented by 300 and Chapter X by 417 references to the scientific literature concerned with the history and development of bacteriology. These chapters should serve as a helpful guide and a splendid bibliography for the surgeon seeking light on the bacteriological problems that confront him.

In Chapter XI, Bacterial Entrance into the Human Body, the author indicates the various potential routes by which bacteria gain a foothold in the tissues—the skin and respiratory tract, the alimentary tract, etc.—and presents illustrative cases with excellent illustrations of gross specimens and microscopic sections.

In Chapters XII–XVII, Bacterial Establishment within the Human Body, Bacterial Spread through the Human Body, "Bacterial Symbiosis," "Bacterial Antagonism," "Bacterial Symbiosis," "Bacterial Antagonism," "The Defense of the Human Body against Bacterial Infection," and "The Mechanism of the Secondary Defenses of the Body," the author presents in a comprehensive fashion the theories and ascertained facts concerning bacteria and their action on inanimate matter and living organisms. Bacterial growth and living and their production of toxic substances and metabolism are spread with well illustrated examples from case histories, bacteriological studies and laboratory studies of bacterial and clinical examples of the new well known antibiotics—all are well presented with numerous references to the literature.

usually poorly informed persons, including many doctors should read this book.

Many passages will bear close reading and re-reading. Some of the prose is excellent. And it is excellent because of its sincerity directness, and clarity. The book is written in easy clear language, and while as the author states, no attempt has been made to lay down hard and fast rules for neurosurgical care (that varying with the policies of the individual surgeon) yet the basic plan of care as outlined serves as a safe guide for the young physician and the interested nurse. JOHN MARTIN

THE small book *Physical Treatment of Injuries of the Brain and Allied Nervous Disorders*² by K. M. Hearn represents the honest efforts of the author a physical therapist, to apply her own concept of what is basically essential and effective in physical therapy for the patient with a brain injury. Her theme is "Teach the patient how to do it for himself." She apparently puts little faith in the use of massage, passive exercise, and other standard forms of therapy leading to rehabilitation. So far as the book goes, it shows by elementary illustrations and English which is almost too simple and informal, some of the steps by which patients can be taught confidence and to carry out co-ordinated movements with their strength which has hitherto been present but misguided. The book gives the impression of being merely a chapter in a larger book on various techniques in physical therapy. There is little that is actually original in it, it is tiresome reading. It does not contain much instruction from page to page.

THE HOSPITAL CARE OF NEUROSURGICAL PATIENTS. By Wallace B. Hamby, M.D., F.A.C.S. and ed. Springfield, Illinois, Charles C Thomas, 1944.

PHYSICAL TREATMENT OF INJURIES OF THE BRAIN AND ALLIED NERVOUS DISORDERS. By K. M. Hearn. Baltimore: The Williams & Wilkins Co., 1947.

because of a repetition of method of instruction, and it is doubted if it will fill any wanted information for well trained American therapists. JOHN MARTIN

IN the volume, *Identification of Tumors*³ by Nathan I. Chandler Foot, a new approach has been used to delineate the pathology of tumors. Before using this text, it is essential to read the preface. Here, the author establishes the basis for his different presentation.

There is a specific aim for simplicity. Controversial matter is eliminated. There is a division into two parts: one, the neoplasms of general distribution and the second the neoplasms of special systems and organs. For some reason tumors of the cardiovascular system are considered in part one. There is a section at the end which may be used to systematize the histologic diagnosis of various new growths. There is a chapter on the technical methods of fixation and staining which, to this reviewer is unnecessary.

The organization pursues a set pattern, the source, the site, age and sex, gross appearance, microscopic appearance, differential diagnosis, and prognosis. In most instances, there is a photomicrograph in black and white. In general, emphasis is laid upon the microscopic picture.

The major flaw in this entire volume is the use of heterogeneous classifications for the various systems. They must be those of the author. These classifications are confusing to trained pathologists and must be more so to the persons for whom the book was written. Many contain combinations of clinical and pathologic terms to the detriment of both. The outline of breast tumors is particularly distressing and that of the skin is somewhat obsolete.

It is recommended that when this text is revised the classifications be simplified in conjunction with the purpose as defined in the preface and that the sections on technical methods and the tabulations be discarded. With these changes, and even in this present issue if the factors mentioned are ignored, the book will serve a distinctly useful purpose in acquainting the interested though untrained man in the morphology of human neoplasms.

M. C. WHEELLOCK.

TO present in a few paragraphs an adequate appreciation of a volume of 700 pages which represents the results of 30 years of conscientious study of careful experiment, and of wide clinical experience in the care of surgical infections is the formidable task which faces one in reviewing Metteney's excellent *Treatise on Surgical Infections*. No one familiar with the development of surgical practice during the last quarter of a century but would agree wholeheartedly with Whipple's splendid tribute in the

IDENTIFICATION OF TUMORS. ESSENTIAL GROSS AND MICROSCOPIC PATHOLOGIC FEATURES SYSTEMATICALLY ARRANGED FOR EASIER IDENTIFICATION. By N. Chandler Foot, M.D. Philadelphia, London, Montreal. J. B. Lippincott Co., 1944.

TREATISE ON SURGICAL INFECTIONS. By Frank H. Metteney, M.D. New York: Oxford University Press, 1948.

introduction since Lister's time no surgeon has studied so intensively and has made so many original contributions to the subject of the bacteriology of infection and inflammation requiring surgical therapy as has Dr Meleney in the past twenty five years.

The volume opens with a historical chapter on bacterial activity in its relation to life and an account of the slow awakening of men of medicine to the importance of inflammatory disease and the futility of treating it by destructive agents. Hospital gangrene in the Civil War is considered at some length with quotations from Jones *Surgical Memoirs of the War of the Rebellion* that describe cases conforming closely to the typical picture of gas gangrene of rapidly spreading streptococcus infection with gangrene of bacterial synergistic gangrene and of chronic undermining ulcer. The two latter conditions illustrated in color in the frontispiece are of especial significance because they continued to baffle surgeons for many years after the Civil War and only in recent years was their true character finally recognized and a successful plan of treatment developed as a result of Meleney's long continued bacteriological and experimental studies. The chapter closes with an appreciation of Pasteur and Lister and of their fundamental contributions to surgical science.

In Chapters II, III and IV *Surgical Infections and their Classifications*, *Sterile Technique* and *Sterilization* the author differentiates 'surgical' from 'medical' infections, and classifies surgical infections by various criteria—by the final outcome by the time and manner of onset and with post-operative infections, by the site or body system chiefly involved. Under *Sterile Technique* the many potential sources of contamination of operative wounds are considered and methods of preventing contamination discussed in detail. The larger part of the 30 pages on *Sterilization* is devoted to the problem of sterilization of air by ultraviolet radiation of the effects obtained and of the practical applications involved.

Chapter V by Edwin J. Pulaski on *Antiseptics and Disinfection in Relation to Surgical Infections* includes a concise discussion of the mode of action of antiseptics and a comprehensive discussion of the many varieties of antiseptics and disinfectants beginning with the surface antiseptics and continuing with the dyes, the ammonium compounds, the halogens, the metallic salts, the oxidizing agents, the phenols, and finally the sulfonamides and antibiotics. Though the many antiseptics discussed are not purposefully presented in chronological order of their development or discovery the reader gains a vivid picture of the constant evolution and progress that have come with the passing years in this important phase of surgery.

In Chapters VI and VII on *Infection in Clean Operative Wounds* and *Infection in Accidental Wounds* the author discusses on the basis of his wide personal observations and experience the im-

portance of adequate masking of careful records of wound healing and postoperative infection, of the importance of the type of suture material and its complete sterilization and (in Chapter VII) the results of the studies on the care of wounds and burns made under the direction of the National Research Council during the war years. Though the latter have had wide publicity and evoked much thoughtful discussion many men are still reluctant to accept the thesis that chemotherapeutic agents which are consistently helpful in overcoming spreading infection and which often produce dramatic results when given by mouth or parenterally do not necessarily prevent or control infection when applied locally in contaminated or infected wounds. The explanation, however, becomes increasingly clear in the later chapters which deal with bacterial establishment and spread in the human body.

Miss Balbina Johnson, long an able associate in the Bacteriological Research Laboratory at the Presbyterian Hospital, contributes two important chapters IX and X,—*The Bacteria That Produce Surgical Infections* and *Methods for Bacterial Cultivation*. The latter is not intended to be a complete manual of bacteriologic technique. It represents a résumé of techniques that have been used and found satisfactory in the study of surgical infections in the Bacteriological Research Laboratory of the Presbyterian Hospital. How much thought and effort Miss Johnson has brought to her task is evidenced by the fact that Chapter IX is documented by 300 and Chapter X by 41 references to the scientific literature concerned with the history and development of bacteriology. These chapters should serve as a helpful guide and a splendid bibliography for the surgeon seeking light on the bacteriological problems that confront him.

In Chapter XI, *Bacterial Entrance into the Human Body* the author indicates the various potential routes by which bacteria gain a foothold in the tissues—the skin, the respiratory tract, the alimentary tract, etc.—and presents illustrative cases with excellent illustrations of gross specimens and microscopic sections.

In Chapters XII–XVII, *"Bacterial Establishment within the Human Body"*, *Bacterial Spread through the Human Body*, *Bacterial Synergism*, *Bacterial Antagonism*, *The Defense of the Human Body against Bacterial Infection* and *The Mechanism of the Secondary Defenses of the Body* the author presents in a comprehensive fashion the theories and ascertained facts concerning bacteria and their action on inanimate matter and living organisms. Bacterial growth, evolution and metabolism, the production of toxic substances, the manner of bacterial spread with well illustrated examples from case histories, bacterial synergism as exemplified by laboratory studies and clinical examples, the laboratory studies of bacterial and other biological antagonisms that eventually led to the discovery of the now well known antibiotics—all are well presented with numerous references to the investiga-

usually poorly informed persons, including many doctors, should read this book.

Many passages will bear close reading and re-reading. Some of the prose is excellent. And it is excellent because of its sincerity directness and clarity. Brief passages descriptive of little ward events could have been written only by a person both keen and honest. One may feel that with her second book Miss Barton has quietly reached maturity as a writer.

JOHN MARTIN

THE first edition of *The Hospital Care of Neurosurgical Patients* appeared eight years ago and in that interval it has been popular with internes, residents and nurses who it seems, are almost all ways puzzled by it not in actual fear of the problems of neurosurgical care. The present edition is some what enlarged, but yet it does not pass the convenient manual size. Certain additions have been made concerning the relations of the house officer to the patient, the attending surgeon, and other personnel in his own and other departments. There is added a discussion of the use of the antibiotics, developed since the first edition and the subjects of intervertebral disc protrusion and prefrontal lobotomy are covered briefly but adequately for the purposes of the book. The organization of the book has been improved. Certain minor errors in grammar and terminology are still present in the second edition. The book is written in easy clear language, and while, as the author states, no attempt has been made to lay down hard and fast rules for neurosurgical care (that varying with the policies of the individual surgeon) yet the basic plan of care as outlined serves as a safe guide for the young physician and the interested nurse.

JOHN MARTIN

THE small book *Physical Treatment of Injuries of the Brain and Allied Nervous Disorders* by K. M. Hara represents the honest efforts of the author, a physical therapist, to apply her own concept of what is basically essential and effective in physical therapy for the patient with a brain injury. Her theme is "Teach the patient how to do it for himself." She apparently puts little faith in the use of massage passive exercise, and other standard forms of therapy leading to rehabilitation. So far as the book goes, it shows, by elementary illustrations and English which is almost too simple and informal, some of the steps by which patients can be taught confidence and to carry out co-ordinated movements with their strength which has hitherto been present but misguided. The book gives the impression of being merely a chapter in a larger book on various techniques in physical therapy. There is little that is actually original in it, it is tiresome reading, it does not contain much instruction from page to page.

because of a repetition of method of instruction, and it is doubted if it will fill any wanted information for well trained American therapists. JOHN MARTIN.

IN the volume, *Identification of Tumors* by Nathan I. Chandler Foot, a new approach has been used to delineate the pathology of tumors. Before using this text, it is essential to read the preface. Here, the author establishes the basis for his different presentation.

There is a specific aim for simplicity. Controversial matter is eliminated. There is a division into two parts: one, the neoplasms of general distribution and the second the neoplasms of special systems and organs. For some reason tumors of the cardiovascular system are considered in part one. There is a section at the end which may be used to systematize the histologic diagnosis of various new growths. There is a chapter on the technical methods of fixation and staining which, to this reviewer is unnecessary.

The organization pursues a set pattern the source the site age and sex, gross appearance, microscopic appearance differential diagnosis, and prognosis. In most instances, there is a photomicrograph in black and white. In general, emphasis is laid upon the microscopic picture.

The major flaw in this entire volume is the use of heterogeneous classifications for the various systems. They must be those of the author. These classifications are confusing to trained pathologists and must be more so to the persons for whom the book was written. Many contain combinations of clinical and pathologic terms to the detriment of both. The outline of breast tumors is particularly distressing and that of the skin is somewhat obsolete.

It is recommended that when this text is revised the classifications be simplified in conjunction with the purpose as defined in the preface and that the sections on technical methods and the tabulations be discarded. With these changes, and even in this present issue, if the factors mentioned are ignored the book will serve a distinctly useful purpose in acquainting the interested though untrained man in the morphology of human neoplasms.

M. C. WHEELLOCK.

TO present in a few paragraphs an adequate appreciation of a volume of 700 pages which represents the results of 30 years of conscientious study of careful experiment, and of wide clinical experience in the care of surgical infections is the formidable task which faces one in reviewing McEwen's excellent *Treatise on Surgical Infections*. No one familiar with the development of surgical practice during the last quarter of a century but would agree wholeheartedly with Whipple's splendid tribute in the

IDENTIFICATION OF TUMORS. ESSENTIAL GROSS AND MICROSCOPIC PATHOLOGIC FEATURES SYSTEMATICALLY ARRANGED FOR EASIER IDENTIFICATION. By N. Chandler Foot, M.D. Philadelphia, London, Montreal, J. B. Lippincott Co., 1944.

TREATISE ON SURGICAL INFECTIONS. By FRANK LAMONT McEWEN. M.D. New York: Oxford University Press, 1948.

introduction since Lister's time no surgeon has studied so intensively and has made so many original contributions to the subject of the bacteriology of infection and inflammation requiring surgical therapy as has Dr Meloney in the past twenty five years.

The volume opens with a historical chapter on bacterial activity in its relation to life and an account of the slow awakening of men of medicine to the importance of inflammatory disease and the futility of treating it by destructive agents. Hospital gangrene in the Civil War is considered at some length with quotations from Jones *Surgical Memoirs of the War of the Rebellion* that describe cases conforming closely to the typical picture of gas gangrene of rapidly spreading streptococcus infection with gangrene of bacterial synergistic gangrene and of chronic undermining ulcer. The two latter conditions, illustrated in color in the frontispiece are of especial significance because they continued to baffle surgeons for many years after the Civil War and only in recent years was their true character finally recognized and a successful plan of treatment developed as a result of Meloney's long continued bacteriological and experimental studies. The chapter closes with an appreciation of Pasteur and Lister and of their fundamental contributions to surgical science.

In Chapters II, III and IV *Surgical Infections and their Classifications* Sterile Technique and Sterilization the author differentiates "surgical from medical infections, and classifies surgical infections by various criteria—by the final outcome by the time and manner of onset and with post operative infections, by the site or body system chiefly involved. Under Sterile Technique the many potential sources of contamination of operative wounds are considered and methods of preventing contamination discussed in detail. The larger part of the 80 pages on Sterilization is devoted to the problem of sterilization of air by ultraviolet radiation of the effects obtained and of the practical applications involved.

Chapter V by Edwin J. Pulaski on "Antisepsis and Disinfection in Relation to Surgical Infections" includes a concise discussion of the mode of action of antiseptics and a comprehensive discussion of the many varieties of antiseptics and disinfectants, beginning with the surface antiseptics and continuing with the dyes the ammonium compounds the halogens the metallic salts, the oxidizing agents the phenols, and finally the sulfonamides and antibiotics. Though the many antiseptics discussed are not purposefully presented in chronological order of their development or discovery the reader gains a vivid picture of the constant evolution and progress that have come with the passing years in this important phase of surgery.

In Chapters VI and VII on "Infection in Clean Operative Wounds" and "Infection in Accidental Wounds" the author discusses on the basis of his wide personal observations and experience the im-

portance of adequate masking, of careful records of wound healing and postoperative infection, of the importance of the type of suture material and its complete sterilization and (in Chapter VII) the results of the studies on the care of wounds and burns made under the direction of the National Research Council during the war years. Though the latter have had wide publicity and evoked much thoughtful discussion many men are still reluctant to accept the thesis that chemotherapeutic agents which are consistently helpful in overcoming spreading infection and which often produce dramatic results when given by mouth or parenterally do not necessarily prevent or control infection when applied locally in contaminated or infected wounds. The explanation however becomes increasingly clear in the later chapters which deal with bacterial establishment and spread in the human body.

Miss Balbina Johnson long an able associate in the Bacteriological Research Laboratory at the Presbyterian Hospital contributes two important chapters IX and X,—"The Bacteria That Produce Surgical Infections Diseases and Methods for Bacterial Cultivation. The latter "is not intended to be a complete manual of bacteriologic technique. It represents a résumé of techniques that have been used and found satisfactory in the study of surgical infections in the Bacteriological Research Laboratory of the Presbyterian Hospital." How much thought and effort Miss Johnson has brought to her task is evidenced by the fact that Chapter IX is documented by 300 and Chapter X by 41 references to the scientific literature concerned with the history and development of bacteriology. These chapters should serve as a helpful guide and a splendid bibliography for the surgeon seeking light on the bacteriological problems that confront him.

In Chapter XI "Bacterial Entrance into the Human Body" the author indicates the various potential routes by which bacteria gain a foothold in the tissues—the skin the respiratory tract, the alimentary tract, etc.—and presents illustrative cases with excellent illustrations of gross specimens and microscopic sections.

In Chapters XII–XVII "Bacterial Establishment within the Human Body" "Bacterial Spread through the Human Body" "Bacterial Synergism" "Bacterial Antagonism," "The Defense of the Human Body against Bacterial Infection," and "The Mechanism of the Secondary Defenses of the Body" the author presents in a comprehensive fashion the theories and ascertained facts concerning bacteria and their action on inanimate matter and living organisms. Bacterial growth evolution and metabolism, the production of toxic substances the manner of bacterial spread with well illustrated examples from case histories bacterial synergism as exemplified by laboratory studies and clinical examples the laboratory studies of bacterial and other biological antagonisms that eventually led to the discovery of the now well known antibiotics—all are well presented with numerous references to the investiga-

tions of the many scientists who have shared in the advances that have been made in the effort to solve the many and baffling problems involved in an understanding of microscopic and ultramicroscopic life and activity.

Chapters XVI and XVII, "The Defense of the Human Body against Bacterial Infection" and "The Mechanism of the Secondary Defenses of the Body" are especially interesting both because of the historical background presented and the excellent portraits of the men who made outstanding contributions to the study of immunity and because of the clear exposition of the cellular and humoral factors involved in body immunity.

In Chapters XVIII XXII "Surgical Principles in the Treatment of Infection," "Chemotherapy in Surgical Infections," "The Treatment of Surgical Infections with Zinc Peroxide," "The Bacteriophage Therapy of Surgical Infections" and "Antibiotic

Therapy in Surgical Infections," the author presents a summary of the principles of prevention and treatment of infection as applied in surgical practice today and of the results that have been obtained with the modern weapons at the surgeon's command. Chapter XXII closes with a brief and very modest reference to bacitracin, the antibiotic that was developed in the author's laboratory.

It is only simple truth to say that this comprehensive treatise so many years in the making will long serve both as an inspiration and guide to the student and practitioner of surgery. One can be very certain as Whipple has said, that only those who have worked with him can understand the time and effort that he has given to these bacteriological studies, and from these efforts the entire surgical profession and the patients for whom they are caring have benefited and will continue to benefit through the coming years.

COLLECTIVE REVIEW

THE SURGICAL PHYSIOLOGY OF THE SYMPATHETIC NERVOUS SYSTEM WITH SPECIAL REFERENCE TO CARDIOVASCULAR DISORDERS

R. H. GOETZ, M.D., Cape Town, South Africa

ORIGINALLY performed for the relief of epilepsy, glaucoma, migraine, and exophthalmic goiter, surgery on the sympathetic nervous system and its indications have undergone considerable modification since its introduction at the end of the last century, by Alexander (1889), Jonnesco (1896), and Jaboulay (1899). The credit for being the first to realize the potential value of sympathetic interruption in the treatment of vasospastic disorders goes to Jaboulay (1899). It was he who developed periarterial sympathectomy and the operation was later popularized by his pupil, Leriche (1913). However, as a result of our better understanding of the peripheral sympathetic pathways (Kramer and Todd, 1914; Woollard and Norrish, 1934), periarterial sympathectomy has since been entirely replaced by ganglionectomy and lately by preganglionic ramisection.

Originally, the indications for sympathectomy were few, and the operation was considered difficult to perform. It was carried out only by surgeons who had done a considerable amount of research in this field and were thus familiar with all the anatomical and physiological aspects of the subject. Within recent years, however, the indications for sympathectomy are continuously becoming more numerous and more clearly defined and the approach to the sympathetic system has

been very much simplified. As a result, the operation has been added to the repertoire of most general surgeons, many of whom must be out of touch with recent scientific developments and knowledge of the recognized prerequisites for successful operation. Thus only can it be explained that the results obtained have been extremely varied, and, in fact, diametrically opposed in well known clinics. This is best illustrated by quoting Samuels (1934). In my experience these operations (sympathectomy and ganglionectomy) have no place whatsoever in the treatment of gangrene or in any phase of thromboangitis obliterans, and in the latest edition of his textbook on diseases of the peripheral arteries (1940) "The magnitude of the procedure and the great operative risk as well as a fairly high mortality certainly do not justify its performance in either thromboangitis obliterans or arteriosclerosis. This is entirely opposed to our experience and that of many other clinics. Our results have always been very gratifying provided the operation was based on definite indications. I have, however, to state emphatically that the operation must not be carried out as a last resort and that no operation is able to revive an already gangrenous limb!

The extrapentoneal approach to the lumbar sympathetic, as described by Leriche (1926, 1933) and by Pearl (1937) and the transthoracic approach to the thoracic sympathetic as first described by Goetz and Marr (1944) have certainly reduced the magnitude of the operation, and in

From the Department of Peripheral Vascular Diseases, Groote Schuur Hospital, and the Surgical Research Department, University of Cape Town.

our series of over 300 consecutive sympathectomies¹ carried out during the last 14 years, there has been not a single operative death.

A sound knowledge of the anatomy and of the physiology of the field in question is even more essential for carrying out a successful sympathectomy than for most other operations. Yet this is made difficult by the fact that there are few short treatises presenting the subject from the surgeon's point of view and the available charts of the sympathetic pathways do not furnish the information essential to the surgeon. We have therefore endeavored to present in this article such facts of the anatomy and applied physiology of the sympathetic nervous system as are of importance to the surgeon.

When we say *sympathetic* nervous system, we use the words in the narrow sense. *i.e.*, we do not include the *parasympathetic* nervous system. Furthermore, we shall be dealing almost exclusively with the motor the efferent side of the sympathetic arc, leaving the afferent or sensory part entirely out of consideration, with the exception of the afferent fibers to the heart.

HISTORICAL

The first account of the ganglia of the sympathetic nervous system and of the splanchnic nerves was given by Galen in the second century (Sheehan, 1936) and a clear anatomical concept of the sympathetic chain and its connections was already known to Etienne (1545) Eustachio (1552) and Willis (1664). The vascular (sympathetic) nerves, however were not discovered until the famous experiments of Claude Bernard in 1852.

Etienne, Eustachio and Willis all gave the sympathetic chain a cerebral origin (similar to the cranial nerves) a mistake later corrected by the French surgeon, François Pourfour du Petit in 1727 after he had ascertained that the fibers in the carotid canal were ascending instead of descending nerve filaments.

The term "sympathetic" was introduced by Winslow (1732) and Bichat (1800) was the first to correlate the sympathetic nervous system with the metabolic functions of the body. He noticed to use his own words, that the "nerves of the ganglia are distributed everywhere to the circulatory system," and that "it is only with the arteries that they are introduced into the organ." (Sheehan 1936). It was, however, only following the discovery of nonstriated muscles by Johannes Mueller (1834) and the demonstration of their presence in arteries by Koelliker (1846) that

Claude Bernard could discover the vasomotor nerves and their tonic effect on the blood vessels (1851). Only later was it recognized that the pilorectors (Schiff 1870) and the sweat glands (Luchsinger 1877 1880) were also innervated by the sympathetic system.

The credit for recognizing that the sympathetic outflow originates in the thoracolumbar region only and for first postulating the existence of two antagonistic systems of nerves for the control of the involuntary musculature goes to Gaskell (1886). Langley (1898) introduced the term "autonomic nervous system" and (1893) gave us the concept of preganglionic and postganglionic neurons, the practical importance of which has only recently been fully realized.

When Langley (1901) discovered that the injection of epinephrine into the blood stream acts like sympathetic stimulation, and Elliot (1913) found that the suprarenal medulla receives a preganglionic sympathetic supply. It became clear that the suprarenal gland forms an integral part of the sympathetic nervous system. This sympathico-adrenal system has been designed to act as a single unit in case of emergency to ensure the integrated action of the body toward changes in its internal and external environment (Cannon 1920, 1928).

The sympathetic nervous system first attracted the attention of surgeons about 50 years ago.

THE SYMPATHETIC REPRESENTATION IN THE CORTEX

Although the physiological and clinical literature contains numerous reports concerning the central control of cardiovascular functions, very little is known about the exact cortical representation of the autonomic nervous system. The evidence furnished by earlier authors, that cerebral stimulation alters the heart rate and blood pressure (Schiff 1875 Danilewski 1875) loses much of its value since Bard (1929) has demonstrated that it can be "accounted for on the basis of spread of strong, stimulating currents to subcortical regions," resulting in an unphysiological discharge. A similar objection holds good for the value of such observations as that by Zenner and Kramer (1909) who reported disappearance of the pulse from the right wrist while attempting to remove a meningioma apparently in the left frontoparietal region.

Recent investigations, not subject to such criticism, have shown that there are apparently no separate cortical areas for sympathetic and parasympathetic reactions. In the cat, dog, and monkey the autonomic system is affected as a whole from one area of the cortex, and the question

¹This figure does not include the patients who have undergone trans-splanchnic sympathectomy for hypertension.

Fig. 1. Diagram of sympathetic pathways to structures of the head and neck and oculosupillary apparatus, with special reference to preganglionic pathways. The uninterrupted preganglionic fibers are constant pathways; the interrupted ones are not present in all cases.

whether we get a sympathetic or parasympathetic response depends entirely upon the physiological state of the animal at the time of stimulation (Crouch and Thompson 1939). Watts and Fulton (1934) could show in monkeys that stimulation of the premotor area produced cardiovascular effects as well as increase in intestinal peristalsis. On the other hand, excessive sympathetic activity such as pooting increase in heart rate, increased production of adrenaline, loss of bladder control gastric hypomotility and intestinal stasis followed by intussusception, have been described following the bilateral extirpation of the premotor area (Watts and Fulton, 1934; Fulton *et al.*, 1934; Kennard 1945). Removal of the premotor area in monkeys also paralyzes the mechanism for reflex vasodilatation in the corresponding limb. Such experimental animals, when placed in a warm atmosphere, will exhibit normal reflex vasodilatation in all extremities except the affected one which remains cool because vasodilatation does not take place. From experiments in cats, monkeys, and the chimpanzee, Hufn and Green (1936) and Green and Hoff (1937) concluded that there is a mechanism by which the cortex can influence the state of the cardiovascular system, and the distribution of the blood to various regions of the body. Through this mechanism the cortex may bring about a finer adjustment of the activity of the heart and circulation in accordance with the exigencies of the external environment and the immediate activities of the skeletal musculature. Excitation of the motor cortex results in a redistribution of blood decreasing the supply of the abdominal viscera but increasing that to those parts which would be made active by the simultaneous excitation of the motor efferent pathways from the same areas of the cortex.

Although caution has to be observed when applying experimental findings in laboratory animals to man, nevertheless, evidence is accumulating that in man too the motor area of the frontal lobe is sympathicomotor and exerts a definite influence on the cardiovascular system via the lower autonomic centers. Emotional disturbances and blood flow which is dependent upon the integrity of the sympathetic pathways (Goetz 1943, 1946). Persons have been observed who seemed to have voluntary control over their sympathetic functions (Clymer 1870; Maxwell 1902). Lindsley and Sassman (1938) reported on one such patient who was able to produce voluntary piloerection, associated with an increase in heart rate, depth of respiration, and blood pressure as well as dilatation of the pupils. Simultaneous records of elec-

trical potentials from the premotor and an independent region showed characteristic changes over the premotor area only during the period interpreted this as evidence of autonomic representation in the premotor area of the cortex in man. Just as severance of somatic cortical control results in the removal of inhibitions so does the liberation of the hypothalamic nuclei from their cerebral connections result in an increase in vasomotor, pilomotor and sudomotor activity. Removal of the cortex in cats leads to spontaneous outbursts of motor activity resembling responses to rage and fear for which the term sham rage has been suggested by Cannon and Britton. Head and Holmes (1911) originally assumed that loss of cortical inhibition was the underlying lesion in the thalamic syndrome. However this interpretation has been questioned (Lashley, 1938). Symptoms similar to sham rage have recently been described by Sjögquist (1941) and Wortis and Maurer (1942) in patients with epileptic seizures and fol-

our series of over 300 consecutive sympathectomies¹ carried out during the last 14 years, there has been not a single operative death.

A sound knowledge of the anatomy and of the physiology of the field in question is even more essential for carrying out a successful sympathectomy than for most other operations. Yet this is made difficult by the fact that there are few short treatises presenting the subject from the surgeon's point of view and the available charts of the sympathetic pathways do not furnish the information essential to the surgeon. We have therefore endeavored to present in this article such facts of the anatomy and applied physiology of the sympathetic nervous system as are of importance to the surgeon.

When we say *sympathetic nervous system*, we use the words in the narrow sense, i.e. we do not include the *parasympathetic nervous system*. Furthermore, we shall be dealing almost exclusively with the motor, the efferent, side of the sympathetic arc, leaving the afferent or sensory part entirely out of consideration, with the exception of the afferent fibers to the heart.

HISTORICAL

The first account of the ganglia of the sympathetic nervous system and of the splanchnic nerves was given by Galen in the second century (Sheehan, 1936) and a clear anatomical concept of the sympathetic chain and its connections was already known to Etienne (1545) Eustachio (1552) and Willis (1664). The vascular (sympathetic) nerves, however, were not discovered until the famous experiments of Claude Bernard in 1852.

Etienne, Eustachio, and Willis all gave the sympathetic chain a cerebral origin (similar to the cranial nerves) a mistake later corrected by the French surgeon, François Pourfour du Petit in 1727 after he had ascertained that the fibers in the carotid canal were ascending instead of descending nerve filaments.

The term "sympathetic" was introduced by Winslow (1732) and Bichat (1800) was the first to correlate the sympathetic nervous system with the metabolic functions of the body. He noticed, to use his own words, that the "nerves of the ganglia are distributed everywhere to the circulatory system," and that "it is only with the arteries that they are introduced into the organ" (Sheehan 1936). It was, however, only following the discovery of nonstriated muscles by Johannes Mueller (1834) and the demonstration of their presence in arteries by Koelliker (1846) that

Claude Bernard could discover the vasomotor nerves and their tonic effect on the blood vessels (1852). Only later was it recognized that the piloerectors (Schiff 1870) and the sweat glands (Luchsinger 1877-1880) were also innervated by the sympathetic system.

The credit for recognizing that the sympathetic outflow originates in the thoracolumbar region only and for first postulating the existence of two antagonistic systems of nerves for the control of the involuntary musculature goes to Goddell (1886). Langley (1898) introduced the term "autonomic nervous system" and (1893) gave us the concept of preganglionic and postganglionic neurons, the practical importance of which has only recently been fully realized.

When Langley (1901) discovered that the injection of epinephrine into the blood stream acts like sympathetic stimulation, and Elliot (1913) found that the suprarenal medulla receives a preganglionic sympathetic supply, it became clear that the suprarenal gland forms an integral part of the sympathetic nervous system. This sympathico-adrenal system has been designed to act as a single unit in case of emergency to ensure the integrated action of the body toward changes in its internal and external environment (Cannon 1900, 1928).

The sympathetic nervous system first attracted the attention of surgeons about 50 years ago.

THE SYMPATHETIC REPRESENTATION IN THE CORTX

Although the physiological and clinical literature contains numerous reports concerning the central control of cardiovascular functions, very little is known about the exact cortical representation of the autonomic nervous system. The evidence furnished by earlier authors, that cerebral stimulation alters the heart rate and blood pressure (Schiff 1875; Danilewski 1875) loses much of its value since Bard (1939) has demonstrated that it can be accounted for on the basis of spread of strong, stimulating currents to subcortical regions, resulting in an unphysiological discharge. A similar objection holds good for the value of such observations as that by Zenner and Kramer (1909) who reported disappearance of the pulse from the right wrist while attempting to remove a meningioma apparently in the left frontoparietal region.

Recent investigations, not subject to such criticism, have shown that there are apparently no separate cortical areas for sympathetic and parasympathetic reactions. In the cat, dog, and monkey the autonomic system is affected as a whole from one area of the cortex, and the question

¹This figure does not include the patients who have undergone transdiaphragmatic splanchnicectomy for hypertension.

disappeared after extirpation of the stellate ganglion. The phenomenon is, therefore a true sympathetic response.

A vasoconstrictor center in the caudal, and a vasodilator center in the oral, part of the hypothalamus has been postulated by Beattie (1932). By recording the discharges from the preganglionic neurons to the cervical sympathetic during stimulation of the hypothalamus Brook and Pitts could establish that the hypothalamus is not directly connected to the spinal sympathetic motor neurons but that the medullary sympathetic centers are interposed and may actually buffer the effect of hypothalamic stimulation.

The evidence which is accumulating concerning hypothalamic control in man seems to agree well with these findings in animals. White (1940 [200]) found, during operation on 5 conscious patients that electrical stimulation of the region of the paraventricular nucleus of the hypothalamus produced abrupt acceleration of the heart rate (up to 160 in one patient) accompanied by a moderate rise in the blood pressure. Similarly, stimulation of the anterior hypothalamus in the region of the preoptic nucleus caused bradycardia. Grinker and Serota (1938) on transphenoidal stimulation of the hypothalamic region, could demonstrate acceleration of the heart rate and respiration increase in vasomotor tone rise in the blood pressure dilatation of the pupils, sweating and contraction of the bladder.

In addition to these direct observations on the human hypothalamus, there are numerous clinical observations which point in the same direction. Tumors and other lesions which compress or destroy the walls of the third ventricle frequently cause disturbances of autonomic functions. One of the patients with a hypothalamic tumor observed by Peet and Kahn (1936) developed, amongst other symptoms severe vasoconstriction with cyanosis and sweating of the extremities simulating Raynaud's syndrome. A patient observed by Penfield (1929) who had a tumor of the choroid plexus in the third ventricle, had attacks of what Penfield called diencephalic autonomic epilepsy i.e., attacks of cutaneous vasodilatation of the face and arms salivary profuse sweating, pilomotor activity dilatation of the pupils increase in the heart rate, spasm of the sphincters, and rise in the blood pressure. A similar symptomatology was later reported by McLean (1934) in a case of tumor in the wall of the third ventricle. Sjögquist (1941) observed this syndrome with acute obstruction of the cerebrospinal circulation and Page (1935) reported on 11 patients with severe, essential hypertension simulating diencephalic stimulation.

Sjögquist is of the opinion that Penfield's diencephalic autonomic epilepsy is the result of an acute distention of the third ventricle which produces stimulation of the autonomic centers lying within its wall.

lowering destruction of the cortical centers from carbon monoxide poisoning and insulin hypoglycemia. Similarly Chevalier (1867) Eulenburg and Landolt (1876) and Gowers (1883) had already noted vasomotor disturbances in cases of hemiplegia, and numerous authors have since clearly described differences between the normal and paralyzed extremity in color, skin temperature, blood pressure, sweating, and pilomotor reactions due to interruption of inhibitory fibers connecting the cortex to the vasomotor centers in the hypothalamus and the medulla (Bastian, 1886; Rossolimo 1895; Régnard, 1913; Danilewsky *et al.* 1926; 1931; Brickner 1930; Olsen, 1933; Munkofski 1933; Popper, 1933; and Uprus *et al.*, 1935). More recently Pilcher, Wynnt, and Carney (1941) demonstrated unilateral sympathetic overactivity following blocking of the left middle cerebral artery by a large embolus. They, too, interpreted this as a release phenomenon of cortical inhibitions.

THE HYPOTHALAMIC CONTROL OF THE SYMPATHETIC

There is a vast literature dealing with evidence of sympathetic representation within the hypothalamus and the wall of the third ventricle. Stimulation of the posterior nuclei in animals results in widespread sympathetic activity with all its characteristic responses, such as rise in blood pressure and heart rate, pupillary dilatation, retraction of

nictitating membrane, whitening of the palpebral fissure, erection of hair, sweating, abolition of gastrointestinal peristalsis, contraction of the bladder and emotional excitement (Karpus and Krendl, 1909; 1918; 1928; Ranson and Magoun, 1933; Khat Magoun, and Ranson, 1935; Khat, Anson, Magoun, and Ranson 1935; Stavsky, 1936; Ectors *et al.* 1938; Hare and Geobagan, 1939; Walker 1940 and Pitts *et al.* 1941). Houszay and Molinelli (1923) and Magoun *et al.* (1937) have demonstrated that there is secretion of adrenaline as well. All these cardiovascular responses are independent of descending pathways from the cerebral cortex (Morrison and Rioch 1937; Magoun 1938) and are not influenced by the extirpation of the hypophysis and the adrenals (Karpus and Krendl, 1927; Stavsky 1936). They are however promptly abolished by resection of the thoracic sympathetic chain and the injection of a sympathetic paralyzant, such as ergotamine tartrate (Jaeger and Isogart, 1935). They are, therefore, the result of stimulation of a projection system taking its origin within the hypothalamus.

Further evidence of hypothalamic control of cardiovascular functions was furnished by Beattie, Brow and Long (1930), who produced ventricular extra systoles by stimulating the posterior part of the lateral wall of the third ventricle. This was corroborated by Khat *et al.* (1934) and by Van Bogaert (1935) who showed that the extra systoles were not affected by section of the vagi but

THE HYPOTHALAMIC CONTROL OF THE SYMPATHETIC

There is a vast literature dealing with evidence of sympathetic representation within the hypothalamus and the wall of the third ventricle. Stimulation of the posterior nuclei in animals results in widespread sympathetic activity with all its characteristic responses, such as rise in blood pressure and heart rate pupillary dilatation, retraction of

nictitating membrane widening of the palpebral fissure erection of hair sweating, abolition of gastrointestinal peristalsis, contraction of the bladder and emotional excitement (Karpus and Kreidl 1909 1918, 1928 Ranson and Magoun, 1933 Kabat Magoun, and Ranson, 1935 Kabat, Anson Magoun, and Ranson 1935 Stavsky 1936 Ectors *et al* 1938 Hare and Geobegan, 1939 Walker 1940 and Pitts *et al* 1941) Housay and Mollinell (1925) and Magoun *et al* (1937) have demonstrated that there is secretion of adrenaline as well. All these cardiovascular responses are independent of descending pathways from the cerebral cortex (Aforsson and Bloch 1937 Magoun 1938) and are not influenced by the extirpation of the hypophysis and the adrenals (Karpus and Kreidl, 1927 Stavsky 1936) They are however promptly abolished by resection of the thoracic sympathetic chain and the injection of a sympathetic paralyzant, such as ergotamine tartrate (Jaegher and Bogart, 1935) They are, therefore the result of stimulation of a projection system taking its origin within the hypothalamus.

Further evidence of hypothalamic control of cardiovascular functions was furnished by Beattie, Brow and Long (1930), who produced ventricular extra systoles by stimulating the posterior part of the lateral wall of the third ventricle. This was corroborated by Kabat *et al* (1934) and by Van Bogart (1935) who showed that the extra systoles were not affected by section of the vagi but

Evidence of these centers in man is still scarce and unconvincing. Starling (1925) first suggested that persistent hypertension may be the result of local asphyxia in the medulla. Various other authors (Nordmann and Mueller 1932, Salus 1932, Raab 1934) have demonstrated changes in the cytology of the medulla in neurological patients who prior to death suffered from rising blood pressure which was *not* due to cardiovascular or renal pathology. They believe that these changes are of considerable significance with regard to the pathogenesis of hypertension.

Today it can be regarded as certain that in man there is bulbar representation of sweating, erection of hair and dilatation of the pupils and that a well localized bulbar area controls the sympathetic outflow to the entire vascular tree, i.e. arteries and arterioles as well as the veins, including the spleen. Its tonic activity may be increased or decreased by afferent nerve impulses or by variations in its blood supply as well as by changes in the carbon dioxide tension (Raab 1929). There is, in addition, evidence that centers controlling the cardiac activity are in close relation to these centers of vasomotor activity. The proximity of the vasomotor center to the respiratory center has long been established and, indeed, respiratory fluctuations are often imposed upon the stream of sympathetic vasomotor impulses which can easily be demonstrated in plethysmographic records of the peripheral blood flow (Goetz, 1943, 1946).

THE SPINAL CENTERS AND THE THORACOLUMBAR OUTFLOW OF THE SYMPATHETIC

Surgeons are usually more familiar with the centers of sympathetic activity situated in the spinal cord than with the higher supraspinal centers. From the higher centers, vasomotor, sudomotor and pilomotor fibers descend along the dorsal fasciculus and the vestibulospinal tracts into the anterolateral columns of the spinal cord. There they establish synapses with the ganglion cells in the lateral horns constituting the spinal sympathetic motor centers. The axons of these ganglia in the lateral horn are medullated and proceed to the corresponding sympathetic paravertebral ganglia via the anterior roots and the rami communicantes to synapse with ganglion cells in the paravertebral ganglia. These white (medullated) fibers are known as preganglionic fibers. The axons of the ganglion cells in the paravertebral ganglia (unmedullated, hence gray fibers) reach the effector organs, either by joining the spinal nerves as in the somatic regions, or by joining the blood vessels, as in the visceral (splanchnic) areas.

Fig. 8. Dorsal aspect of same patient as in Figures 3 and 4, but following bilateral removal of the second thoracic ganglion.

It is important to realize that in man the sympathetic centers in the spinal cord, i.e. the lateral horn extend only from T_1 to L_2 (Harman, 1898, Pick and Sheehan, 1946)—hence the term thoracolumbar division of the sympathetic. The paravertebral sympathetic ganglia, on the other hand, extend right down to the coccygeal region and up into the neck where, through fusion, there are only three instead of eight cervical ganglia. They are the inferior cervical ganglion being the fused seventh and eighth cervical ganglia, the middle cervical ganglion, being a fusion of the fifth and sixth, and the superior cervical ganglion, representing the upper four cervical ganglia. There is, therefore, no sympathetic outflow through the anterior roots in the cervical region, nor in the lumbar and sacral region below L_2 . The preganglionic fibers to the cervical ganglia and to the ganglia below L_2 must reach them along the sympathetic cord, i.e. via the first thoracic ganglion in the case of the cervical ganglia and via L_1 in the case of the lumbar and sacral ganglia (Figs. 1, 9, and 15).

Harman (1900) had already noticed that the limit of the preganglionic outflow may vary according to the fixation of the brachial plexus. As the plexus moves up a segment (prefixed) the preganglionic outflow moves up one segment to C_7 and in the case of a postfixed brachial plexus the second thoracic ganglion may become the

Fig. 5.

over the anterior aspect of the chest and in the face. A Horner's syndrome.

Fig. 7. Same patient as in Figures 5 and 6 following bilateral removal of the second thoracic ganglion. Note complete symmetry of loss of sweating in the dorsal aspect indicating that pattern is characteristic in this patient.

Summarizing the available evidence of hypothalamic control of sympathetic function, we can say that it points clearly to the presence of two distinct mechanisms, one in the posterior portion producing a co-ordinated response of numerous *sympathetic* reflexes, and the other in the anterior portion producing a similar co-ordinated response of *parasympathetic* outflow (Cushing, 1932; Beatle, 1932). Each of these seems to be directed toward the maintenance of a constant internal environment. The cortex however exerts a controlling (inhibitory) influence upon these mechanisms (*vide p. 419*). In addition, we must not lose sight of the fact that the hypothalamus, and thus the sympathetic nervous system, through its influence upon the pituitary body, is working hand in glove with the entire endocrine system and thus takes part in the control of the latter.

THE SYMPATHETIC CENTERS IN THE MEDULLA

Following the discovery of the vasomotor nerves by Claude Bernard workers in Ludwig's laboratory were able to demonstrate that these vasomotor nerves were under the influence of higher centers in the medulla (Owajnikow 1871; Dittmar

1873). They found that stimulation of the central end of the sciatic nerve resulted in a rise in blood pressure, even after all the brain above the medulla had been removed. More recently Ranson (1916) and Ranson and Billingsley (1916) exploring the floor of the fourth ventricle with stimulating electrodes, identified a vasoconstrictor and a vasodilator center as well as an area which may correspond to what Porter (1915) had termed the "vasotonic" (in contrast to the vasoreflex) center. These findings of Ranson and his coworkers were challenged by Scott (1925) but were confirmed recently in carefully controlled experiments by Alexander (1946). He could produce a reduction in the blood pressure and cardioaccelerator tone by removing the portion of the medulla located as the pressor center i.e. in the lateral reticular formation of the rostral two-thirds of the medulla. He also demonstrated a depressor center which includes the greater part of the medial reticular formation in the caudal half of the medulla, and demonstrated once more that the pressor reflex which is produced by stimulation of the sciatic nerve depends upon the integration of the bulbar centers.

employing the preganglionic sympathectomy technique. The whole problem is at present being investigated by us and we are making use of more comprehensive methods of measuring the blood flow and vasomotor tone than were employed by previous authors.

Fatherree and his coworkers demonstrated that removal of the ganglia (postganglionic sympathectomy) in man does not produce nearly as great a sensitization of smooth muscle as it does in the monkey. This gives added point to our contention that the technique of the operations on the sympathetic system should be based on physiological data obtained from man and not from animals.

Knowledge of the preganglionic sympathetic outflow in man is still incomplete and often in correctly stated, largely because it has been deduced by indirect methods or by attempts to apply to man the findings in laboratory animals.

This is further complicated by the fact that it has been found that the fibers of one anterior root may run up and down the paravertebral chain and that one preganglionic sympathetic neuron may synapse with as many as six to nine (Langley 1900) or even twenty postganglionic neurons (Billingsley and Ranson 1918). This explains why stimulation of one white ramus, containing preganglionic fibers of one cord segment only causes sympathetic effects over many skin segments. For instance, stimulation of the anterior root of Th_2 causes erection of hair over an area extending from Th_1 to S_4 , i.e. on the whole leg and on the abdomen to well above the umbilicus. It causes sweating in all the lumbar and sacral dermatomes. Similarly stimulation of the anterior root of Th_4 causes erection of hair over an area extending from C_4 to Th_4 (Foerster 1936) or to give another example, stimulation of one anterior root containing preganglionic fibers to the hand (see page 428) results in simultaneous vasomotor changes in all fingers of that hand (Ray *et al.*, 1943). From such evidence it appears that each ganglion cell in the paravertebral ganglia is innervated by preganglionic fibers from a great number of spinal segments. It is in this way that the characteristic diffuse discharge from the sympathetic is achieved. From all this emerges the point that, unless we achieve interruption of all preganglionic pathways, there can be no permanent loss of sympathetic activity to the area in question.

Therefore every operation on the sympathetic, in order to be successful has to be (1) anatomically complete (2) preganglionic in type, and (3) extensive enough to guard against future regeneration of interrupted fibers.

Fig. 10 Diagrammatic representation of sympathetic outflow supplying the upper extremities, according to various authors. For explanation see text. Black—outflow present in all patients shaded—outflow present in some. The arrows indicate that lower limit was not determined. Numbers across top of chart refer to the reference of the authors. O.C.—own cases.

Any modern schematic representation of the sympathetic system should take due consideration of these principles which constitute the prerequisites for successful operations on the sympathetic nervous system.

THE SYMPATHETIC INNERVATION OF THE VARIOUS REGIONS

To make practical the afore-mentioned principles, a chart of the sympathetic innervation of the extremities and various organs in man should furnish the surgeon with the following information (a) the origin and course of the preganglionic fibers, (b) their synapsis with the postganglionic neuron, and (c) the course and distribution of the postganglionic fibers. We therefore deal with the various regions and trace the pathways in that order.

The sympathetic supply of the skin of the head, the neck and the oculo-pupillary fibers

a. Origin of the preganglionic fibers—commonly in the lateral horn of Th_1 and Th_2 , occasionally in C_8 and in Th_{1-4} (Figs. 1 and 2)

b. Course of the preganglionic fibers—ascending in the sympathetic trunk.

c. Synapsis of the preganglionic with the postganglionic neurons—in the superior cervical sym-

Fig. 9. Diagram showing preganglionic and postganglionic sympathetic fibers to the upper extremity. The uninterrupted preganglionic fibers are present in all cases; the interrupted ones are present in some cases. The postganglionic fibers indicated by a cross-line signify Kuntz's nerve.

highest cranial outflow Foerster (1936) and Goets and Marr (1944) have made similar observations. Correspondingly L_1 instead of L_2 may become the lowest segment with sympathetic outflow.

Thus the peripheral sympathetic consists of three components: (1) preganglionic fibers taking their origin in the lateral horn (medullated, hence white ram), (2) paravertebral ganglia and (3) postganglionic fibers (nonmedullated, hence gray ram).

PHYSIOLOGICAL CONSIDERATIONS AND PREREQUISITES FOR SUCCESSFUL SYMPATHECTOMY

Toward the end of the last century various authors demonstrated that in animals extirpation of the ganglia and degeneration of the sympathetic nerves induce an increased response of the affected organ to adrenaline. This sensitization phenomenon is found in all smooth muscle which is under the control of adrenergic nerve impulses.

It has been reported for the denervated heart (Cannon, Lewis, and Britton 1936) the pupil (Meltzer and Auer 1904; Meltzer 1904) and the nictitating membrane (Cannon and Rosenbluth, 1937, 1939) as well as for the peripheral vascular tree (Elliot, 1905; Freeman, Smithwick, and White 1934; White, Okelberry, and Whitelaw 1936; Atlas, 1941[8]). Increased sensitivity to adrenaline is registered after interruption of either preganglionic or postganglionic fibers (Elliot, 1905; Grant, 1935; Ascroft, 1937). The postganglionic operation, however, renders the structures from two to three times more sensitive than preganglionic section (Hampel 1935). Ascroft calculated that the sensitivity increases three times following section proximal to the ganglion, but ten times following the postganglionic interruption. McCloskie *et al.* (1937) found that this hyperreaction may become sufficiently intense to produce necrosis of the skin when adrenaline is injected intracutaneously in the lower forelimb of a dog after removal of the stellate ganglion.

Hypersensitivity to adrenaline following ganglionectomy or interruption of the postganglionic fibers constitutes a complicating factor in cases in which surgery is contemplated. It may actually bring a technically well planned operation into disrepute. It has been blamed for the relatively poor results of cervicothoracic ganglionectomy for the relief of vasospasm (Telford, 1935; Smithwick, 1936; Cannon, 1937; Learmonth, 1937) and some authors (White, Okelberry and Whitelaw, 1936; Smithwick, Freeman, and White, 1934) believe that it accounts for the recurrence of vasospasm in Raynaud's phenomenon. Ascroft (1937) and White (1940[303]) have actually demonstrated in monkeys that the good results of a preganglionic ramsection can be vitiated if the corresponding ganglia are subsequently resected. Ganglionectomy has therefore been entirely replaced by preganglionic ramsection, as suggested by Telford (1935) and by Smithwick (1936). For this reason the exact knowledge of the origin and the course of the preganglionic fibers to the various regions has become as essential as their postganglionic supply. There are, however, authors who do not subscribe to this view. Fetherree and Allen (1938) and Fetherree, Adson, and Allen (1940) showed that, although there was an increase in the sensitivity of the blood vessels to adrenaline after sympathectomy there was no material difference whether the operation was of the preganglionic or postganglionic type. Grimson (1946) points out that the unsatisfactory results obtained in the upper extremities following sympathectomies have not been materially improved by operations

employing the preganglionic sympathectomy technique. The whole problem is at present being investigated by us and we are making use of more comprehensive methods of measuring the blood flow and vasomotor tone than were employed by previous authors.

Fatherree and his coworkers demonstrated that removal of the ganglia (postganglionic sympathectomy) in man does not produce nearly as great a sensitization of smooth muscle as it does in the monkey. This gives added point to our contention that the technique of the operations on the sympathetic system should be based on physiological data obtained from man and not from animals.

Knowledge of the preganglionic sympathetic outflow in man is still incomplete and often in correctly stated largely because it has been deduced by indirect methods or by attempts to apply to man the findings in laboratory animals.

This is further complicated by the fact that it has been found that the fibers of one anterior root may run up and down the paravertebral chain and that one preganglionic sympathetic neuron may synapse with as many as six to nine (Langley 1900) or even twenty postganglionic neurons (Billingsley and Ranson 1918). This explains why stimulation of one white ramus, containing preganglionic fibers of one cord segment only causes sympathetic effects over many skin segments. For instance, stimulation of the anterior root of Th_3 causes erection of hair over an area extending from Th_1 to S_4 , i.e. on the whole leg and on the abdomen to well above the umbilicus. It causes sweating in all the lumbar and sacral dermatomes. Similarly stimulation of the anterior root of Th_4 causes erection of hair over an area extending from C_6 to Th_4 (Foerster 1936), or, to give another example, stimulation of one anterior root containing preganglionic fibers to the hand (see page 428) results in simultaneous vasomotor changes in all fingers of that hand (Ray *et al.* 1943). From such evidence it appears that each ganglion cell in the paravertebral ganglia is innervated by preganglionic fibers from a great number of spinal segments. It is in this way that the characteristic diffuse discharge from the sympathetic is achieved. From all this emerges the point that, unless we achieve interruption of all preganglionic pathways, there can be no permanent loss of sympathetic activity to the area in question.

Therefore every operation on the sympathetic, in order to be successful has to be (1) anatomically complete (2) preganglionic in type, and (3) extensive enough to guard against future regeneration of interrupted fibers.

pathetic ganglion except for a few terminating in the middle cervical ganglion.

d. Course of the postganglionic fibers—they join the internal carotid for the structures of the orbit, the external carotid for the skin of the face, and the salivary glands and the cervical plexus (C_1 to C_4) for the skin of the neck. (Some fibers arising in the superior cervical ganglion join the phrenic nerve—Hovelacque, 1927.)

e. Comment. Exact information as to the sympathetic supply to the head and neck and to the ciliospinal centers in man is available from studies of Foerster (1936, 1939) Thomas (1936) Head and Riddoch (1917) and more recently from Hyndman and Wolkin (1943) Ray *et al.* (1943) and Sheehan (1941). The data are tabulated in Figure 2. Foerster stimulated the anterior roots and actually observed the individual qualities of sympathetic action. These were his findings (Fig. 2).

a) If a strong sympathetic response was obtained on stimulation of the anterior root of Th_1 , stimulation of Th_2 caused a less definite response and vice versa. Dilatation of the pupil may be observed after stimulation of the roots of C_4 , Th_1 and Th_2 , but if on stimulation of C_4 a definite effect is observed, there will be none from stimu-

lation of Th_2 , and vice versa. Stimulation of Th_1 therefore, invariably produced a strong dilatation of the pupil in all cases. As for the vasoconstrictor and sweating fibers, they arose in the first and second thoracic segments only while pilorection could be obtained on stimulation of the anterior root of C_4 as well. Thomas' findings were slightly different—he obtained sweating, dilatation of the pupil, and pilorection on stimulation of the anterior root of C_4 down to Th_2 . Ray and his co-workers, on the other hand, tested for dilatation of the pupil only and in 1 of 10 patients they found a contribution from C_4 . Th_1 contributed dilator fibers to the pupil in all patients, while Th_2 failed to do so in 3. In 4 of 10 patients dilatation was obtained on stimulation of the anterior root of Th_1 and 2 of these responded to stimulation of Th_2 as well. Different results were recorded by Hyndman and Wolkin (1943) who, after studying 5 cases, came to the conclusion that no sympathetic fibers supplying the skin structures of the face and the upper extremity leave the first thoracic root in man.

Our own experience goes to show that neither the orthodox view of Foerster and Thomas, nor the recently advanced idea of Hyndman and

Fig. 13. Sweating pattern characteristic for some patients following bilateral removal of Th_1 , indicating complete interruption of sweat fibers to the extremities but no loss of sweating in face, neck and trunk.

Fig. 14. Complete absence of sweating of hand following removal of left second thoracic ganglion.

Wolkin, is entirely correct. We have removed the dorsal sympathetic chain below Th_1 (below the stellate ganglion) in 42 cases, and in 18 cases (43%) thermoregulatory sweating of the face and neck was abolished (Figs. 3, 4, 11 and 12). This would conform to the findings of Hyndman and Wolkin, and confirm the fact that there was no sympathetic outflow from Th_1 . In the remaining 57 per cent the skin structures of the face and neck were not denervated (Figs. 5, 6 and 7) which indicated that in these patients Th_1 was not the highest source of sympathetic outflow. Although there was this difference in the sympathetic supply of the skin in our cases there were no differences in the sympathetic supply of the oculopupillary apparatus. In all patients in whom the sympathetic chain was excised below the stellate ganglion, Horner's syndrome was absent,¹ which indicated that the central connection of the oculopupillary apparatus via Th_1 is constant (Figs. 3 to 7). These findings have been confirmed by direct stimulation during operation (unpublished data). Our own investigations have taught us that sympathetic sweat, pilorector vasocon-

strictor and pupillary fibers supplying the face and neck need not arise from the same segments and that no conclusions can be drawn from the absence or presence of any one as to the functional state of the others. This fact is of particular importance when assessing the recovery of sympathetic activity following sympathectomy. So far no differences between the sympathetic innervation of the left and right side have been found. In fact, the exact symmetry of functional loss was remarkable (Figs. 7, 8, and 12) if one considers the differences often found in the anatomy at operation.

From this description of the sympathetic supply of the face and neck it is apparent that removal of the stellate ganglion (inferior cervical and first thoracic) constitutes in all cases a complete and almost pure preganglionic ramisection for the sympathetic fibers to the head and neck. It results in ipsilateral loss of sweating, loss of vasomotor tone, and Horner's syndrome in all cases. Sectioning of the anterior roots or white rami of both Th_1 and Th_2 will result in complete preganglionic interruption of the sympathetic pathways in about 60 per cent of the cases. In the remaining cases there will be an outflow from C_4 , Th_2 and Th_1 (Fig. 1)

¹Although occasionally a slight degree of transient Horner's syndrome obtained in a few cases.

Fig. 5. Sympathetic pathways supplying the lower extremities. The interrupted preganglionic fibers are present in some patients only.

If the cord is sectioned below Th₁ as well 90 per cent of the cases should be completely (preganglionic) sympathetomized and therefore should also show a positive Horner's syndrome. Sectioning of one white ramus alone, either Th₁ or Th₂, will in all cases interrupt but few of the sympathetic fibers, and no significant functional impairment can be expected. Removal of the second thoracic ganglion does not produce a Horner's syndrome and in 43 per cent of the cases it produced complete preganglionic sympathetomy of the skin structures of the face and neck. In the remaining cases there was no loss of any of the sympathetic functions in the face and neck. In any operation which leaves the preganglionic outflow from Th₁ intact, Horner's syndrome will not occur.

The sympathetic innervation of the upper extremities

a. Origin of preganglionic fibers—commonly in the lateral horn of Th₁ to Th₄, or ∞ , occasionally from Th₅ as well.

b. Course of preganglionic fibers—ascending in sympathetic trunk.

c. Synapses of preganglionic with postganglionic neurons—in inferior cervical and first thoracic ganglion (stellate ganglion) with few syn-

apses in the second and third thoracic and the middle cervical ganglion.¹

d. Course of postganglionic fibers the vast majority take their origin in the stellate ganglion, a few arise in the ganglia just mentioned, and all join the roots of the brachial plexus.¹

e. Comment The origin of the preganglionic fibers to the upper limbs is still a matter of considerable dispute and sympathectomy of the hands is still of doubtful permanent value. First, it is interesting to note that the segmental outflow of vasoconstrictor and sudomotor fibers should come from as low as Th₄₋₅ (Fig. 9). However from the surgical viewpoint the upper level of the outflow is of greater importance. Our present knowledge is largely based on the early experiments of Langley and Bayliss and Bradford. It is precisely here that the application to man of results obtained in animals has been confusing and actually misleading. Kuntz, Alexander and Furculo (1938) demonstrated in cats a sympathetic outflow from Th₁ and suggest the same for man. Sheehan and Marrani (1942) could not confirm this in the monkey (Th₁ being the highest spinal outflow) and, as for man, numerous authors, from carefully controlled experiments, have given Th₁ as the upper limit (Foerster 1936 Atlas, 1941 Hyndman and Wolkin 1943 Goets and Marr 1944). Ray et al (1943) had occasion to stimulate the anterior dorsal root in man and found an outflow from Th₁ only in 1 of 11 patients (and in this 1 only on one (left) side, Th₁ having been the highest outflow on the right). Therefore, it appears justified to accept, for the present, Th₁ as the upper limit of the preganglionic sympathetic outflow to the upper extremities in man. The available evidence is summarized in Figure 10.

From all that has gone before, it is clear that removal of the stellate and second thoracic ganglions is a postganglionic sympathectomy. In order to achieve a preganglionic rhizotomy the stellate ganglion must remain intact and removal of only the second ganglion seems to be the ideal operation, particularly in patients who do not have Kuntz's nerve. I.e., no postganglionic fibers arise in the second paravertebral ganglion. This would occur in four-fifths of the cases, but in the other fifth some postganglionic neurons will necessarily be removed with the second thoracic ganglion. The sympathetic fibers of the second

¹As per case of his cases Kuntz (1936) found a large branch passing from the second ganglion to the brachial plexus, and Perlow et al. (1933) demonstrated Kuntz's nerve in 11 of 21 cases. More recently Kuntz and Kuntz (1942) described a further branch which arose from the third thoracic ganglion, joining the second thoracic nerve central to the origin of Kuntz's nerve and contributing sympathetic fibers to the brachial plexus.

thoracic ganglion however, apparently supply the upper arm only the hand being innervated only by fibers from the stellate ganglion. Indeed, Hyndman and Wolkun (1942), and we ourselves (Goetz and Marr 1944) have suggested removing the second thoracic ganglion only in order to achieve sympathectomy of the upper extremities, and in all cases this has resulted in immediate and complete sympathetic denervation, both as regards sweating (Figs. 11 to 14) and central vasoconstrictor tone. However as Ray *et al* (1943) have shown, an outflow from Th_1 occurs in less than 1 of 10 patients and in these this procedure is therefore not complete. There exists no method of determining such a case beforehand. Therefore, we have recently started to stimulate during operation the cut ends of the sympathetic trunk, the various rami, and the bed from which the sympathetic chain has been removed, and to record the vasomotor responses in the respective limb with our plethysmographic method (Goetz 1946). We thus hope to prove to our satisfaction during operation that the resection carried out is physiologically complete.

It has to be admitted that sympathectomy for the upper extremities has not given the ideal results so easily achieved in the lower limbs. After Kuntz's nerve had been described, the original operation (stellatectomy) was extended to include the second thoracic ganglion (Adson and Brown, 1929). This did not materially alter the situation, and sensitization was then regarded as the cause of the relapses. It was then that Telford (1935) and Smithwick (1936) demonstrated that the arm can be completely denervated by dividing the preganglionic rami of the second and third thoracic ganglia and cutting the sympathetic trunk below the third ganglion (preganglionic ramisection). The immediate results of this operation were far superior to those following stellatectomy. The late results still did not compare favorably with those following denervation of the lower extremities. Regeneration was then held responsible for the late relapses (Simmons and Sheehan, 1939; Smithwick 1940). In order to prevent this, Smithwick recommended intraspinal root section of Th_2 and Th_3 and cutting of the trunk below the third paravertebral ganglion, as well as covering of the phane. Finally the free lower end of the trunk was transplanted into the muscle of the wound (Smithwick 1940). White and Hamlin (1945) recently suggested the use of tantalum instead of the silk cylinder. Even such procedures did not prevent the recurrence of vasoconstrictor tone. The issue has by no means been clarified by a

Fig 16 Roentgenogram of patient in whom bilateral splanchnicectomy has been performed for hypertension. Note clips fixed by surgeon during operation on all sympathetic fibers cut. On the left side the last clip is above the intervertebral disc between L_4 and L_5 and obviously the second lumbar ganglion has not been removed.

recent report of Skoog¹ who drew attention to sympathetic structures termed 'intermediate ganglia' by Hirt, the significance of which had been overlooked in surgical texts. They are microscopic masses of ganglion cells, distributed without any definite rule in the communicating rami to the spinal nerve, often in closest proximity to the latter. Onodi was the first to mention ganglia in the rami communicantes of human embryos. Van der Broek, and Marinesco and Minea confirmed this, the latter pointing out that they are sympathetic in nature. Hirt found these ganglion cells in certain reptiles and coined the term 'intermediate ganglia.' Rossi, Gruss, and Wreite (221 222 223 224, 225 226) studied these ganglia in man and in 1941 Wreite pointed out that it is not impossible that these ganglion cells send postganglionic fibers to the nearby spinal nerve, which may escape during standard sympathetic denervation. Skoog working in Wreite's laboratory de-

¹Reference in this paragraph only are to be found under Additional References.

scribed these ganglia in more detail in the cervicodorsal region of 5 adults. He, like Wreite, assumes that we are dealing with motor ganglion cells and he visualizes two possible pathways by which they receive their preganglionic supply (1) via the sympathetic trunk, and (2) directly from the spinal nerve next to which they are lying. If the former is true then the significance of the intermediate ganglia is less important from the surgical point of view since removal of the chain will automatically denervate them. However if the latter should be correct, then we would be dealing with entirely intraspinal sympathetic pathways, not accessible to the surgeon by the standard methods employed in interrupting the sympathetic supply. Therefore, the intraspinal sympathetic pathways could easily explain failures following the usual operations. However it is important to realize that the ganglia are also found in the lumbar region (Wreite, 223, 225, 226) where sympathectomy after all, is lasting and complete. This strongly supports the concept that the preganglionic supply to these ganglia reaches them via the chain and not directly from the spinal nerve. However further investigations (particularly physiological) concerning these structures are required before a definite opinion can be formed as to their significance in surgery on the sympathetic nervous system.

In 1941 Geohagan and Aidar suggested that recovery of sympathetic tone may be due to reorganization of function within the sympathetic system itself. They cited a case (Ray *et al.*, 1942) in which the ventral roots from the second to the ninth thoracic segment were sectioned. Complete sympathetic denervation of the hand resulted, but after 10 weeks function returned. The authors pointed out that this could not have been due to regeneration on account of the short time interval and they think that pathways were used which before operation did not carry sympathetic impulses to the hand. They suggest that the first thoracic root which, as we have seen, ordinarily carries no vasoconstrictor fibers to the upper extremities, may develop such function after the usual pathways have been interrupted. They put this theory to the test in cats and found that after interruption of all preganglionic pathways to the forepaw, new pathways developed from higher spinal roots which normally contribute no outflow to the upper extremities. It is quite conceivable how this can happen in a case like the one illustrated in Figs. 5, 6 and 13, but it would be more difficult to conceive in the cases in which the structures of the skin of the face and neck have no origin from Th_1 the highest outflow being from

Th_4 only. In this respect it is interesting that Do Takata (1940) suggested extending the original (postganglionic) cervicodorsal sympathectomy to include the intermediate and inferior cervical as well as the first, second, and third dorsal ganglia. In 16 cases in which he followed this procedure, the results were, in his opinion, comparable with those obtained from lumbar sympathectomy. We are preparing a follow up of our series of cases in which the second thoracic ganglion only was removed. Late relapses occurred in some patients from 10 to 12 months after the initial good result. This may have been due to reorganization in the sense of Geohagan and Aidar. We shall have to put this point to the test by subsequent sectioning of the white ramus supplying the stellate ganglion. For the present we have extended our operation to include resection of Th_2 , Th_3 , and Th_4 and in some cases we are following De Takata's (1940) suggestion. The results will be communicated in the near future.

In going through the literature it appears to us that many authors do not fully realize that, as we have pointed out on numerous occasions, the sympathetomized vessel still reacts with constriction to the local application of cold. It is only the central vasoconstrictor impulses, as they occur with emotional strain and excitement, which are abolished by sympathectomy. Raynaud's phenomenon, as produced by the local application of cold, may therefore persist following sympathectomy. The vessels will react as well to direct-acting constrictor substances circulating in the blood. If we keep these facts in mind then our hopes of relieving Raynaud's phenomenon by sympathectomy in every case will be less high and our disappointment less acute.

The sympathetic supply to the thoracic and abdominal wall. This may be quickly disposed of since it is of little clinical importance. The preganglionic fibers arise in the lateral horn of the corresponding segments and reach the paravertebral ganglia where the synapsis of the postganglionic fibers is to be found. The neurons of the latter join the spinal nerves, as is the rule for somatic areas. It appears, therefore, that we have a strictly segmental distribution.

The sympathetic supply to the lower extremities

- Origin of the preganglionic fibers—in the lateral horn of Th_1 to L_4 (a)
- Course of the preganglionic fibers—descending in the sympathetic trunk.
- Synapsis of preganglionic with postganglionic neurons—in L_4 to S_2 for the foot and the lower leg, and in the ganglia of L_1 to L_4 for the thigh and medial aspect of the lower limb.

d. The postganglionic fibers take their origin in the ganglia corresponding to the lumbosacral plexus, i.e. L_4 to S_3 for the sympathetic fibers joining the sciatic nerve, and L_1 to L_4 for the fibers joining the femoral and the obturator nerve.

e. Comment As a rule the lowest preganglionic sympathetic outflow is via the anterior root of L_4 and all lower sympathetic ganglia receive their preganglionic supply via the second lumbar ganglion (Fig 15). The second ganglion therefore holds a key position and its removal results in complete interruption of the sympathetic pathways to all the lower ganglia and, hence, complete sympathectomy of the foot. This is well illustrated by Figures 16 and 17 obtained from a patient who elsewhere underwent transdiaphragmatic splanchnicectomy for hypertension. The clips fixed by the surgeon (Fig 16) indicate that on the right side L_4 was removed, but on the left side the first lumbar ganglion only was resected. Clinically the right leg only was sympathectomized and plethysmographic examination (Fig 17) indicates complete ablation of central vasomotor control on the right and normal sympathetic activity on the left. Incidentally this clearly demonstrates the importance stressed previously (Goetz 1947) of checking every case of splanchnicectomy as to the completeness of the operation.

Since, however, in a small number of cases there is some outflow from L_4 (vide p 423), the standard lumbar sympathectomy for cases of vascular deficiency in the foot and lower leg is removal of the second and third lumbar ganglia which is automatically preganglionic in type (Fig 15) and presents no problems. At Groote Schuur Hospital we do not consider lumbar sympathectomy a serious major operation and it is efficiently carried out by the general surgical staff by means of the extraperitoneal approach on both sides in a one-stage operation. None of the postganglionic fibers is interrupted. They take origin from L_4 downward. Some surgeons remove L_4 as well which as the chart illustrates, is not only unnecessary but it should remain untouched.¹ As for L_1 its removal bilaterally in the male will cause sterility through paralysis of the ejaculatory mechanism. No untoward effects have been recorded in the female. Removal of L_2 and L_3 usually causes loss of sympathetic activity from the knee downward. When L_1 is left intact, an area on the inner aspect of the lower limb to just above the ankle, corresponding to the saphenous

Fig 17 Plethysmographic tracing of the blood flow simultaneously recorded in the two lower extremities of the same patient as in Figure 16. A Blood flow during rest. Upper record—left lower record—right big toe. Resp = respiration. Note pulse volume in the left limb is slightly smaller than in the right one. B Thirty minutes later following body heating. No increase in pulse volume of the right limb (lower record) but marked increase in the pulse volume of the left limb (upper record) indicating release of the vasoconstrictor tone in the latter. C Following local application of heat to the right limb. Note the increase in pulse volume of the right limb, indicating that there is no organic vascular disease present and that the failure to dilate in B was due to interruption of the sympathetic pathways.

nerve arising from the femoral nerve can be mapped out in some cases in which sympathetic control has not been abolished (Figs. 18 to 19). Therefore, we recommend removal of L_1 in the cases in which the question of sterility does not concern the patient. In cases in which the release of vasoconstrictor tone well above the knee has to be aimed at, it is always advisable to remove L_1 . We have however to point out that removal of L_1 to L_4 constitutes a postganglionic sympathectomy for the sympathetic fibers joining the femoral and obturator nerves. So far well over 200 lumbar sympathectomies have been carried out at Groote Schuur Hospital. In each, L_2 and L_3 and occasionally L_4 have been removed. In all cases a complete sympathectomy has been achieved and

¹The arrangement of the ganglia in the lumbar region varies. Great deal, the ganglia fusing with each other often in a complex fashion, and leading to duplication of the intervening trunk, so that recognition of the individual ganglion is often impossible (Perlow and Vehe, 935 Pack and Sherbas, 1946).

is still complete in the patients operated on as long as from 10 to 15 years ago. Reflex vasomotor activity has not recurred in a single case! It appears obvious, therefore, that removal of L_4 in order to prevent regeneration is not justified, removal of L_4 and L_5 being entirely sufficient. Interlumbosacral sympathectomy—a procedure recommended by Danilepohu *et al.* (1933) which consists in sectioning the chain below L_4 , is not to be recommended for reasons obvious from Figure 15.

The sympathetic innervation of the organs in the thorax (in particular of the heart)

a. Origin of the preganglionic fibers—in the lateral horn of Th_1 to Th_{10} .

b. Course of the preganglionic fibers—part of the fibers arising in Th_{1-4} ascend to the cervical ganglia, most of the fibers go to the corresponding paravertebral ganglia.

c. Synapsis of preganglionic with postganglionic neurons—in the three cervical ganglia and the upper five thoracic ganglia.

d. Course of the postganglionic fibers—they arise in the three cervical ganglia and form the three cardiac nerves to reach the cardiac plexus. In addition, there are direct fibers from the paravertebral ganglia to the cardiac plexus.

e. Comment. Surgery of the heart hardly ever calls for interruption of the sympathetic motor fibers, and the surgeon's interest centers around the sensory pathways which join the sympathetic system. Although this article does not deal with the sensory pathways, we cannot fail to mention here surgical procedures on the sympathetic system adopted in the treatment of pain in coronary disease. Certain authors still hold (Reid and Andrus, 1944) that all sensory fibers of the heart can be interrupted by excision of the stellate ganglion. This is definitely not so. The pathways for cardiac pain are essentially the same as those just traced for the motor cardiac fibers (Ionescu *et al.* 1928, White *et al.*, 1933, McEachern *et al.* 1940, Kuntz and Morehouse, 1930). Some fibers ascend via the middle and lower cardiac nerve to the middle cervical and the stellate ganglia and thereafter descend to the upper three thoracic ganglia to reach the cord via the corresponding white rami and posterior roots (Fig. 21). Twice as many fibers, however, run across the posterior mediastinum to reach the upper four to five, possibly six to seven (Saccomanno 1943) thoracic ganglia directly which they pass without interruption to proceed via the white rami to the posterior root ganglia. The superior cardiac nerve apparently does not conduct cardiac pain. Hence, the surgical approach must be either at the thoracic ganglia (White, 1944) or at the white rami (Raney

1939) or alternatively at the posterior roots (Davis, 1933). The latter has the advantage that there is no interference with efferent fibers.

François Franck (1899) was the first to suggest sympathectomy for angina pectoris, and Jönnesco (1920) was the first to carry out the operation in 1916. He removed the entire cervical sympathetic chain, including the stellate ganglion, bilaterally. In the following years this operation was carried out by numerous surgeons who reported good results (Coffey and Brown, 1923, Brown, 1923, Bacon, 1923, Bruening, 1923 and Cutler, 1932). Kerr (1936) reported complete relief of pain in 14 of 30 patients operated on in this manner and Leriche in 1936 advocated stellatectomy for the same purpose. The good results claimed for these procedures are difficult to explain in the light of recent anatomic and physiologic findings. Indeed, Learmonth (1937) and Öchsner and DeBakey (1937) report a large number of failures from cervicothoracic sympathectomy because of the failure to interrupt the direct afferent fibers.

The ideal procedure is obviously resection of the upper four or five posterior roots, which gives consistent relief from coronary pain (Davis, 1933, Haven and King, 1942, Ray 1943). The effectiveness of resection of the upper three thoracic sympathetic ganglia, through which most of the sensory axons run, has been found by White and Smithwick (1941) and White (1944) to approach 100 per cent. In patients who are good enough operative risks there is no evidence that relief from pain has any but a favorable effect. While severe constricting pain which radiates to the precordium and inner arm disappears consistently following the destruction of these pathways, other nonpainful sensations persist, such as a sense of fullness in the upper end of the sternum, vasomotor changes in the face and the neck, palpitations, and dyspnea. Such residual sensations afford an adequate warning signal to the patient, indicating that he is straining his heart. There is evidence that these nonpainful impulses are probably transmitted over the vagus.

Unfortunately the selection of patients who are good enough operative risks to withstand the procedure is not easy and many of the worst sufferers have too poor a coronary circulation to withstand an operation of this nature. In these the alcohol injection into the paravertebral ganglia, as advocated by Mandl (1935) has been the solution (White and White, 1928, Levy and Moore, 1941, White, 1940 [1941], Perlow 1942). As White (1944) has pointed out, interruption of the pathways of pain may have a beneficial effect on the coronary circulation as well.

Fig. 19. Same patient as in Figure 18. Outer aspect of left leg. Note complete absence of sweating of foot.

The sympathetic supply to the abdominal viscera.

a. Origin of the preganglionic fibers—in the lateral horn of $Th_{(4,5)}$ to L_4

b. Course of the preganglionic fibers—they pass through the corresponding paravertebral ganglia to form the three splanchnic nerves. The fibers from L_1 and L_2 reach the aorticorenal plexus directly (Fig. 22)

c. Synapsis of the preganglionic with the postganglionic neurons—in the solar plexus (celiac, superior mesenteric, and aorticorenal ganglia)

d. Course of the postganglionic fibers—they form a plexus around the main blood vessels which they join to reach the various organs.

e. Comment. The solar (celiac) plexus is the large nerve mass on each side of the celiac axis continuous with a network of sympathetic nerves in relation to the aorta. Bichat (1802) considered that the solar plexus constituted the termination of the two great splanchnic nerves. However it is known that the solar plexus receives not only gray and white fibers from the thoracic sympathetic, but also fibers from the lumbar sympathetic, the right vagus, and perhaps from the phrenic nerve (Hovelacque, 1927). The solar plexus comprises a dense meshwork of fibers with aggregates of a number of secondary ganglia in relation to the branches of the aorta. The classic description supposes that there are six well formed individual ganglia, the semilunar (celiac) ganglia, the aor-

tico renal ganglia, and the superior mesenteric ganglia. It must be realized, however that this is only a schematic representation and that the ganglia fuse and split up into many variations which it is not possible to describe in this article.

The sympathetic innervation of the suprarenal gland is also preganglionic in origin, being supplied via the splanchnic and directly from L_1 and L_2 (Elliot, 1913; Hoshi, 1926; Hollinshead, 1936). The preganglionic fibers end in relation to the secretory cells in the medulla. The latter are therefore morphologically comparable to the postganglionic neurons in the paravertebral ganglia. The most convincing evidence to this effect has recently been furnished by Hammond and Yntema (1947). After removal of the neural crest in chick embryos, sympathetic neurons in the paravertebral ganglion chain and the chromaffin cells of the suprarenal medulla were absent.

The splanchnic nerves have gained considerable prominence within recent years on account of the surgical treatment of hypertension, which aims at sympathetic deservation of the splanchnic area.

We know that the splanchnic bed is man's mechanism for maintaining his blood pressure level relatively constant in the lying, sitting, and standing positions. If the splanchnic is well denervated, the blood pressure level should fall as the patient changes from the lying to the sitting and standing positions. Indeed, such a change has

Fig. 20 Efferent sympathetic cardiac pathways.

followed splanchnic resection by laminectomy and anterior root section, although this operation, in addition to interrupting the sympathetic motor pathways, also divides somatic motor nerve fibers. The latter results in extensive muscular paralysis of the abdominal wall.

Several operations have been employed, connected with the names of Pieri (1927) Craig (1934) Adson and Brown (1934) Peet (1935) and Crile (1938). The operation practiced by most surgeons is that devised by Smithwick (1940).

The operative technique should comply with the three cardinal points, viz., it should (1) be anatomically complete (*vide* p. 425) (2) be preganglionic in type, and (3) safeguard against future regeneration. Smithwick suggested transdiaphragmatic removal of the ganglionic chain extending from T_4 down to L_2 and extirpation of a long segment of the greater lesser and least splanchnic nerves, the celiac ganglion to be left intact. Such an operation is followed by postural hypotension, but unless a postural change in blood pressure follows splanchnic resection, it is not certain that the maximum change in blood pressure has been produced. Thorough denervation of the splanchnic bed and removal of the lumbar chain also give a reasonable guarantee that the kidneys and the adrenal glands are denervated as well.

During the operation the kidneys, adrenal glands, and the paravertebral regions should be

Fig. 21 Diagram of afferent (pain) cardiac sympathetic fibers. Not direct branches and absence of pathway via superior cervical ganglion.

carefully explored in order to obtain all possible information regarding renal pathology and to exclude adrenal tumors and paragangliomas.

In discussing the surgical treatment of hypertension, Grimson (1942) states that the fall in blood pressure has been directly proportional to the extent of the sympathectomy and inversely proportional to the severity of the disease. He therefore advocates total sympathectomy which, as he points out (Grimson, Wilson, and Phemister 1937) also prevents neurogenic elevation of the blood pressure as produced by increase in the intracranial pressure. We (Goetz, 1947) have pointed out that the operative procedure suggested by Smithwick does not fulfill the first prerequisite for successful operation, i.e., it is not anatomically complete in that sympathetic pathways from the dorsal ganglia above T_4 , forming the preaortic and esophageal plexuses, are not interrupted. As we have pointed out earlier these plexuses link up with the solar plexus and, we may add, the phrenic nerve which receives its sympathetic supply from the superior cervical ganglion, has been found to send connections to the celiac ganglion. We have drawn attention to the possibility that the body may re-establish sympathetic control of the splanchnic area in this roundabout way (Goetz, 1947) and we felt that such reorganization, rather than regeneration, may account for

the failures in some cases following the Smithwick operation. From the experiments of Geoeagan and Audar (1942) we know that in other regions such re-organization is the rule rather than the exception. There is, therefore, strong evidence in favor of carrying out a more extensive procedure than has originally been suggested by Smithwick, and at Groote Schuur Hospital we aim at total sympathectomy through an incision removing the tenth and part of the ninth rib the sympathetic chain being at present removed from D_3 to L_2 in tact with its connections forming the splanchnic nerves and the direct branches to the organs in the mediastinum and the heart (Fig. 23).

Fig. 23 The anatomical arrangement of preganglionic (interrupted) and postganglionic (uninterrupted) sympathetic pathways to the splanchnic bed.

cardiac failure and cerebral accidents, then the importance of this operation cannot be overestimated.

CONCLUDING REMARKS

Cannon and his coworkers (1929) and McDonough (1939) have demonstrated that an intact sympathetic nervous system is not a *sine qua non* in a protected and constant environment, and totally sympathectomized cats and dogs may thrive under such conditions. The stresses and strains which are met with in the normal existence however make its integrity essential. According to Cannon, whose views have been extremely well expressed by White, we should think of the sympathetic nervous system as an emergency protective mechanism which is not functioning all the time but which is always ready to go into action to combat any variety of adverse circumstance either in the surroundings or in the internal machinery. This co-ordination of the body as a whole to meet changing conditions in its internal and external environment by autonomic adjustment has been called 'homeostasis' by Cannon. Homeostasis frees the individual from the difficult task of paying routine attention to the management of the details of bare existence. Without homeostatic control, the warmblooded animal would be in constant danger of disaster unless always on the alert to correct voluntarily

Those who had expected the Smithwick operation to be a cure all for hypertension must be sadly disappointed. It is obvious that when cardiac and renal function are both significantly impaired, no operation can be successful. Everyone who has had reasonably wide experience with the operation, however, will admit that in some cases it has produced a permanent fall in the blood pressure which for all practical purposes constitutes a cure. Regression of eyeground changes, decrease in the size of the heart, improvement in the electrocardiogram, increase in the renal function, and relief of the symptoms are noted in many cases. The difficulty still arises in selecting the correct patients for operation out of the great number of potential candidates. Smithwick (1944) has published his grading criteria, yet our own experience has shown that they are not as helpful as suggested by him in predicting the ultimate results of the operation. Some patients, who should have responded well according to these criteria, benefited very little or not at all from the operation, while others, on whom the operation appeared to be misplaced gave group 1 responses. It is to be hoped that it will eventually be possible to define the indications for the operation more clearly so that a higher percentage of patients will be benefited by the operation as judged by a persistent and significant fall in the blood pressure. Although it is not yet established that the results will be permanent, at least there is good reason to believe that the hands of the clock can be set back for a number of years in the majority of younger patients with hypertension who have not been permitted to progress to the stage of advanced degenerative changes in the arteries of the kidneys, heart, and brain (White 1944). If it is realized that it is very rare for the increased blood pressure to return spontaneously to normal values, for any length of time and that a large majority of patients with hypertension die at a relatively early age of the sequelae of hypertension, such as

Fig. 13. Two typical specimens of the sympathetic chain and splanchnic nerves as removed by subtotal sympathectomy at Groote Schuur Hospital for hypertension.

what the sympathetic nervous system regulates in a purely automatic fashion.

Some of the most common conditions which arouse sympathetic activity are pain, emotional excitement, extremes of temperature, asphyxia, hemorrhage, strong muscular exercise, dehydration, and hypoglycemia. Furthermore, any form of intense emotion or psychic trauma stimulates a generalized sympathoadrenal discharge. It is such conditions which cause particular strain on the vascular system of patients already suffering from hypertension or from structural vascular disease. On the other hand, we must not lose sight of the fact that the autonomic nervous sys-

tem is not a purely motor system under control of higher centers, but that sensory impulses arising in smooth muscle, ligaments, joints, and glandular tissue, control, to a large extent, sympathetic motor activity in a purely segmental reflex fashion. The indications for sympathectomy then, are to be found among such conditions in which there is either a central or peripheral disturbance of the reflex proprioceptive regulatory function of the sympathetic nervous system. Man, being capable of protecting himself against adverse circumstances and of creating a constant environment for himself can fortunately continue to exist after a large portion, or even the whole, of the sympathetic chain has been removed.

The author gratefully acknowledges the co-operation of all honorary surgeons attached to the Groote Schuur Hospital in referring patients and kindly permitting re-examination following operation.

The expenses of this research were defrayed by the Marais Memorial Research Fund and in part by a grant from the Government Research Council.

I am indebted to Miss L. Coomans for assistance with the preparation of the manuscript and to Mr J. de Villiers, Mr O. McKinnon, and Mr C. C. Goosen for help with the photographs.

I also wish to acknowledge with thanks the permission of the Editor of the South African Medical Journal and the Editor of Clinical Proceedings for inclusion of Figures 1, 4, 11, and 12.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

Eye

Parathyroid Deficiency DONALD J. LYER. *Am. J. Ophth.*, 218, 3, 580.

The ocular syndrome of cataract and papilledema is rare as only 21 cases have been reported in the world literature. The cataract produced by parathyroid deficiency however, is of relatively frequent occurrence. Parathyroid deficiency may be idiopathic, as the result of lack of growth or degeneration of the glands, or as a result of operation. At a latent stage, the symptoms of hyperneuromuscular excitability are present only upon local nerve stimulation or irritation. At a manifest stage the deficiency is characterized by generalized spontaneous convulsions, in addition to ectodermal changes. The neuroectodermal symptoms, i.e. mental disturbances, and increased intracranial and cerebrospinal pressures with papilledema, appear.

The diagnosis of parathyroid deficiency is made by means of the laboratory tests of the blood calcium and phosphorus, added to the signs of excessive neuromuscular irritability. The normal calcium content of the blood varies within the limits of 9 and 11 mgm. per 100 c.c. In cataract tetany or parathyroid deficiency the level drops to 7 or 8, and in manifest tetany as low as 4. The phosphorus content, which is normally between 3 and 4 mgm. is relatively or absolutely increased in proportion to the calcium content. A differential diagnosis must be made from idiopathic epilepsy and brain tumor.

The case of a 53 year-old woman, who was examined because of failing vision, is reported. Years previously she had undergone a thyroidectomy. Since then, she lost her hair her skin was dry and her nails were brittle. Her corrected visual acuity was reduced to 20/100 in the right eye and 20/40 in the left eye. Diffuse posterior subcortical opacities were found in the lenses, and the fundi were normal. There was a slight elevation of the intraocular pressure. On the basis of the presence of the positive Chvostek and Trousseau signs, a low blood calcium (8.1 mgm. per 100 c.c.) and the history, a tentative diagnosis of postoperative parathyroid deficiency was made. During the 3 years following, the lense opacity increased to a mature cataract. The intraocular pressure fluctuated, apparently rising with the reduction of calcium and falling when the calcium returned to a normal level. After a cataract extraction in the right eye, a cyclodialysis operation became necessary later some permanent central corneal opacities developed. An uneventful cataract operation was performed upon the left eye. On the ninth day however, the patient developed a generalized convulsion lasting 4 minutes and preceded

by a loud, piercing scream. From the anamnesis, it was found that the patient had had six similar seizures in the last 5 months. On postoperative examination the patient seemed quite confused, disturbed, and blind. The ophthalmoscopic examination revealed clear media but a papilledema of considerable amount, with parapapillary venous engorgement without hemorrhages. The visual fields were markedly constricted. Roentgenograms of the skull, orbit, and intracranial contents were normal. Immediate improvement began with the administration of dihydrotachysterol and calcium lactate. Convulsions and twitchings ceased after the first day. The mentality cleared. The visual fields improved and the papilledema, though still present, seemed to be reduced considerably at the end of the first week.

MICHAEL LOUVALIAN, M.D.

Pterygium. ERANUEL ROSEN. *Brit. J. Ophth.*, 1941, 3, 300.

A new technique for pterygium surgery is described and illustrated. The pterygium is excised from the cornea with a sharp knife and folded back underneath itself to be sutured under the caruncle. The conjunctiva is closed, horizontally from the becketed end of the pterygium to the limbus.

The advantages offered are

1. The head of the pterygium is brought into contact with the caruncle which is a modified cutaneous structure.
2. The direction of the growth of the pterygium is completely reversed.
3. The episcleral tissue fuses with the episcleral tissue.
4. The pterygium is completely buried.

EARL H. MEIER, M.D.

Obliteration of the Central Artery of the Retina—Partial Recuperation of Vision and Retinographic Appearance (Obliteración de la arteria central de la retina. Recuperación parcial de la visión y aspecto retinográfico). J. LUIS PAVIA and MAURICIO LEE. *Rev. de neuro-oftal. de Mex.* 1947, 22, 97.

The authors state that obliteration of the central artery of the retina has been attributed to many causes, and they review the works of the various authors to date who have attributed obliteration of the retinal central artery to embolism or thrombosis. To these two factors the authors wish to add the factor of angiospasm which is becoming of increasing importance.

The authors think that in patients more than 60 years of age thrombosis and embolism prevail. In those between 55 and 60 years old the principal factor is angiospasm.

Fig 1 (Rosen) This is a diagrammatic representation of the various steps in the operation for pterygium. a, Characteristic pterygium before operation. b Pterygium being severed from the cornea and dissected back to its base. c, Double armed suture placed through pterygium head and emerging from the episcleral side. A small area of conjunctiva is undermined at each limbal area and appears like a small crescent. d Each arm of the suture is passed underneath the pterygium and brought out through the caruncle. The pterygium is separated from the sclera with the scissors at its upper and lower borders. e, The double armed suture is tied over a small rubber button. The upper and lower free edges of the conjunctiva are sutured with three or four single sutures. f The conjunctiva is completely approximated.

Two cases recently studied by the authors are reported. In one of these the authors followed the characteristic changes of the retina with excellent retinographic photographs until the retina slowly returned to normal.

The authors conclude that the essential factor upon which the nutrition of the retina depends is the choreocapillary circulation which may or may not be sufficient to conserve the vision. The result therefore may be intense anemia of the internal layers which may result in loss of transparency and complete atrophy.

W FOSTER MONTGOMERY M D

EAR

A Contribution to the Question of Otitis Media in Infants. ANDRÉ MARÉ *J Lar Otol Lond* 1948 62 207

The author states that it is generally acknowledged that infants during the first year of life are more susceptible to otitis media for two reasons (1) the greater susceptibility of the infant to infection (2) the anatomical peculiarities of the infant middle ear (a) the relatively short wide almost horizontal eustachian tube and (b) the remnants of embryonic middle ear mucosa.

Otitis media in infants is classified as follows (1) Witmarck's otitis media pronatorum, (2) catarrhal and suppurative otitis media. (a) manifest or latent

and (b) primary or secondary to any concurrent infection elsewhere.

The relationship between infection of the gastrointestinal system and otitis is considered reference being made to I. E. Ebbs who found that of 238 infants with gastroenteritis, 81 per cent also displayed otitis. In the symptomatology of otitis media in infants weight loss and gastrointestinal infection are more prominent symptoms and pain in the ear a less prominent symptom of otitis than in older children and adults.

The author attempts to show that the appearance of the ear drum if carefully examined is a reliable guide in making a diagnosis of otitis media in infants and believes there is general agreement that myringotomy should be performed in all cases of obvious or doubtful disease of the tympanic membrane.

One hundred and one cases of suspected otitis media in infants under 1 year of age are surveyed. When otoscopy revealed the slightest deviation from normal myringotomy was done (in 92%) and a diagnosis of otitis media was made in 79 cases (78.2%). In 19.9 per cent of the 79 infants mastoidectomy was performed with a mortality rate of 27 per cent.

The average amount of time required for treatment of the infants with uncomplicated disease was 24 days the time required for treatment of those with complications was 53½ weeks.

The dosage, or incidence of use of penicillin and sulfonamide drugs in the treatment of otitis media in infants is not clearly given; however the author states that the results were rather less effective and very slow as compared to the results in older children. He believes this may indicate that many of these cases are secondary complications of gastro-enteritis. The findings in each case are tabulated.

JOHN J. BALLINGER, M.D.

The Surgery of Otosclerosis (La chirurgie de l'otospongiose) RAYMOND PHILIP J. *med. Bordeaux* 948, 5-63.

The author presents his method of fenestration for the treatment of deafness due to otosclerosis.

The disease process itself is considered as evolving in three periods:

1. A period of invasion of the capsule when treatment is primarily medical.
2. A period of progression toward stapedo-vestibular ankylosis without labyrinthine alteration.
3. A period of labyrinthine atrophy with diminishing bony conduction.

The second period is the surgical phase of the illness in the course of which 80 per cent of those operated upon can recuperate sufficient hearing for normal conversation. Surgical treatment in creating a fistula and new tympanic system betters the hearing and also seems to arrest the evolution of the disease.

The operative technique is described in detail and the complications and end-results are discussed.

EDWARD W. GIBBS, M.D.

The Fenestration Operation E. R. GARNETT PAMEL *Irish J. M. Sc.* 1948, Ser. 6, 45.

The author reports his experiences with the fenestration operation in more than 600 cases. With regards to the selection of cases for operation, Garnett Pamele classifies cases of clinical otosclerosis into three groups in each of which a certain result may be expected.

Group I consists of cases in which the reserve of cochlear nerve function is adequate. The prognosis in this group is that from 80 to 90 per cent of the patients will have restoration of hearing to the practical hearing level.

Group 2 consists of the borderline cases, which show cochlear nerve damage to such an apparent extent that maximum improvement is necessary to obtain a practical hearing level. Success in this group is anticipated in only about 20 to 40 per cent of the cases.

Group 3 consists of the cases with the cochlear nerve so far deteriorated that the chance of improvement from fenestration is practically nil. The author considers paracusis willisiana a sign which should be carefully observed before a patient is selected as suitable for the operation. This is a questionable factor because patients are not always reliable in reporting or recollecting this phenomenon.

In reporting his operative procedure the author emphasizes that hemorrhage must not be allowed to occur and trauma to all tissues must be kept to a minimum. Pentothal anesthesia after heavy premedication is preferred by the author with novocain and adrenaline injected into the site of incision. Magnification is obtained by using the binocular loupe microscope and constant irrigation is employed to wash away bone dust and to keep the field clear of blood. The author states that he uses his own modification of Shambaugh's endochondralized fenestra, which is much longer than either Lempert's or Shambaugh's, and more of the endosteal bone is exposed. The author describes his technique of extensive removal of the periosteal bone which leaves only a thin eggshell layer of the endosteal bone extending posteriorly from the anterior end of the dome of the vestibule over the ampulla and a downward bend of the lateral semicircular canal to the posterior canal.

Garnett Pamele states that he has given up the use of the cartilage stopper and is at present working with solutions of antihistamine agents in an attempt to decrease postoperative labyrinthitis but he does not describe the technique of their use.

The author's experience regarding relief of tinnitus by the operation leads him to expect marked or complete relief in approximately 25 per cent of his cases.

He reports on 100 cases of stopper insertion in which operation was done 2 years previously.

Hearing improved and improvement was maintained in 31 per cent.

CRITERIA FOR GROUPING

	Air Conduction	Bone Conduction Masking	Remarks	Normal and Middle Ear and Present Junctional Tubes	Paracusis Willisiana	Age
Group I	Not below 40 decibels loss up to 20 dB	Not below 40 decibels (by 5) 30 decibels for 10 dB 40 decibels for 20 dB	-- for facts from 30-20 dB	Excellent	++	Best results 15 to 25, but may operate at any reasonable age
Group II	Not below 40 decibels loss up to 20 dB	Not below 40 decibels loss for 5 25 decibels loss for 10 dB 45 decibels loss for 20 dB	-- all facts from 30 to 20 dB 20 dB usually not heard	May have had former Ch. S. O. M.	++	Usually 25-40
Group III	May have 40 dB deafness at any frequency	Usually 40 and 45 are heard	-- for 40 and 45	May or (may not) be present	+ or --	Usually elderly though occasionally in early twenties

Hearing improved and the improvement was lost later in 39 per cent.

Hearing was not improved in 7 per cent.

Hearing became worse in 3 per cent.

The degree of improvement is not specified nor is the final hearing level attained by the patient mentioned.

An interim report (patient operated upon less than 2 years previously) on the author's last 450 cases in the past 18 months under the previously mentioned groupings is as follows:

Group 1 Hearing was improved to the practical level and maintained in 86 per cent.

Group 2 Hearing was improved to the practical level in 33 per cent.

Group 3 In 3 cases no improvement was noted. In the latter series the author has not had a case in which the fistula has completely closed as judged by the fistula sign on probing.

The author emphasizes the importance of detailed follow through records of the operative technique together with standardized audiometric records to all surgeons actively engaged in the fenestration operation.

EUGENE L. DERLACKI, M.D.

NOSE AND SINUSES

Orbital Complications Resulting from Lesions of the Sinuses. AUSTIN T. SMITH and JAMES T. SPENCER. *Ann Otol Rhinol*, 1948, 57, 3.

The authors present 12 cases illustrating infections: mucocoeles, epidermoid cysts and osteomas of the paranasal sinuses responsible for complications of the orbit. The intimate anatomical relationship between the sinuses and the orbit allows for ready involvement of the orbital contents by inflammatory and other lesions of the sinuses.

The diagnostic problem involved in the orbital complications depends upon a consideration of the symptomatology as follows:

1. The symptoms of inflammatory changes in the orbit such as (a) inflammatory edema of the eyelids (b) subperiosteal abscess, a collection of pus between the bony wall and the periorbita, (c) orbital abscess (d) orbital cellulitis and (e) cavernous sinus thrombosis of the anterior or orbital type.

2. The symptoms of disturbances from mechanical causes due to encroachment upon the capacity of the orbit by mucocoeles, pyocoeles, chronic hyperplastic sinusitis, cysts and neoplasms and manifested by displacement and disturbance in the mobility of the globe, injury to the optic nerve, changes in refraction and disturbance in the drainage of tears.

3. The orbital apex or sphenoid fissure syndrome, a syndrome consisting of ptosis, complete ophthalmoplegia, impaired vision and pain corresponding to the ophthalmic division of the fifth nerve which is caused by affection of the vessels and nerves which pass through the superior orbital fissure and the optic foramen.

The authors found in their study that difficulty and delay in diagnosis arose because (1) the sinus

infection was not apparent from symptoms or rhinologic examination (2) a noninflammatory lesion was obscured by inflammatory reaction (3) in spite of a history of sinus infection the focus was elsewhere and (4) lesions of the sinuses such as mucocoeles, cysts or osteomas gave no nasal symptoms and entomias were not manifest until the eye symptoms were marked.

The authors believe that roentgen examination was the greatest single aid in the diagnosis but it must be correlated with the clinical evidence.

As for treatment, inflammatory conditions causing orbital infections are most efficaciously treated with penicillin in adequate dosage given parenterally which largely obviates the previously practiced curative procedures. As for the lesions which cause disturbances by mechanical means the authors advocate surgical incision and drainage through the sinuses into the nose in cases of mucocoeles and hyperplastic lesions or surgical removal of plastic lesions such as osteomas, followed by the establishment of adequate nasal drainage.

In illustrating the problems of diagnosis and therapy the authors reviewed the case histories of (1) 6 cases of the inflammatory group (2) 3 cases of mucocoeles, (3) 1 case of epidermoid cyst of the frontal bone, and (4) 2 cases of osteoma of the frontal and ethmoid sinuses.

MOUTH

Oral Conditions with a Background of Systemic Disease. KURT H. THOMA, DANIEL J. HOLLAND, JR., HOWARD W. WOODBURY, JARRELL G. BURROW, and EDWARD L. SLEPPER. *Oral Surg & Path* 1948, 1, 8.

This article concerns the report of 3 cases of oral disease which represent very dramatic examples of the importance of co-operation between the dental, medical and surgical services for proper diagnosis and treatment of diseases, the first symptoms of which may occur within the oral cavity. The neglect of a complete physical examination in such cases may cause very embarrassing results.

The first case was that of tumor of the maxilla associated with hypoparathyroidism. This case was that of a 62 year-old farmer who was referred to the dental clinic for treatment of a firm nontender, asymptomatic swelling of the left side of the face of 3 weeks duration. This tumor involved the anterior portion of the left alveolar process and caused the left cheek to bulge. It had increased progressively for 3 weeks. The patient was referred by the dental clinic to the laboratory for blood studies after a biopsy of the lesion which came back as a giant-cell

The presumptive diagnosis of hypoparathyroidism was made at this time from the blood studies. Surgical intervention was discouraged and the patient was referred to the medical service of the hospital for further study. At that time the complete medical

The dosage, or incidence of use of penicillin and sulfonamide drugs in the treatment of otitis media in infants is not clearly given; however the author states that the results were rather less effective and very slow as compared to the results in older children. He believes this may indicate that many of these cases are secondary complications of gastroenteritis. The findings in each case are tabulated.

JOHN J. BALLENGER, M.D.

The Surgery of Otosclerosis (La chirurgie de l'otospongiose) RAYMOND PHILIP J and Bordenes 948, 5-63.

The author presents his method of fenestration for the treatment of deafness due to otosclerosis.

The disease process itself is considered as evolving in three periods:

1. A period of invasion of the capsule when treatment is primarily medical.
2. A period of progression toward stapedo-vestibular ankylosis without labyrinthine alteration.
3. A period of labyrinthine atrophy with diminishing bony conduction.

The second period is the surgical phase of the illness, in the course of which 80 per cent of those operated upon can recuperate sufficient hearing for normal conversation. Surgical treatment in creating a fistula and new tympanic system better the hearing and also seems to arrest the evolution of the disease.

The operative technique is described in detail and the complications and end-results are discussed.

EDWARD W. GIBBS, M.D.

The Fenestration Operation. E. R. GARRETT PAMEL Irish J. M. Sc., 1948, Ser. 6 145

The author reports his experiences with the fenestration operation in more than 600 cases. With regards to the selection of cases for operation, Garrett Pamel classifies cases of clinical otosclerosis into three groups, in each of which a certain result may be expected.

Group 1 consists of cases in which the reserve of cochlear nerve function is adequate. The prognosis in this group is that from 80 to 90 per cent of the patients will have restoration of hearing to the practical hearing level.

Group 2 consists of the borderline cases, which show cochlear nerve damage to such an apparent extent that maximum improvement is necessary to obtain a practical hearing level. Success in this group is anticipated in only about 30 to 40 per cent of the cases.

Group 3 consists of the cases with the cochlear nerve so far deteriorated that the chance of improvement from fenestration is practically nil. The author considers paracusis willisiana a sign which should be carefully observed before a patient is selected as suitable for the operation. This is a questionable factor because patients are not always reliable in reporting or recollecting this phenomenon.

In reporting his operative procedure the author emphasizes that hemorrhage must not be allowed to occur and trauma to all tissues must be kept to a minimum. Pentothal anesthesia after heavy premedication is preferred by the author with novocain and adrenaline injected into the site of incision. Magnification is obtained by using the binocular loupe microscope and constant irrigation is employed to wash away bone dust and to keep the field clear of blood. The author states that he uses his own modification of Shambaugh's encephalized fenestra, which is much longer than either Lempert's or Shambaugh's and more of the endosteal bone is exposed. The author describes his technique of extensive removal of the periosteal bone, which leaves only a thin eggshell layer of the endosteal bone extending posteriorly from the anterior end of the dome of the vestibule over the ampulla and a downward bend of the lateral semicircular canal to the posterior canal.

Garrett Pamel states that he has given up the use of the cartilage stopple and is at present working with solutions of antihistamine agents in an attempt to decrease postoperative labyrinthitis, but he does not describe the technique of their use.

The author's experience regarding relief of tinnitus by the operation leads him to expect marked or complete relief in approximately 25 per cent of his cases.

He reports on 100 cases of stopple insertion in which operation was done a years previously.

Hearing improved and improvement was maintained in 51 per cent.

CRITERIA FOR GROUPING

	Air Conduction	Bone Conduction Masking	Rinne	Normal and Middle Ear and Foreign Empatium Tubes	Paracusis Willisiana	Age
Group I	Not below 30 decibel less up to 1924	Not below 30 decibel for 51 30 decibel for 1924 40 decibel for 1948	++ for 1924 from 1925-1948	Essential	++	Best results up to 25 but may operate at any reasonable age
Group II	Not below 30 decibel less up to 1924	Not below 30 decibel less for 51 25 decibel less for 1924 45 decibel less for 1948	++ all facts from 1925 to 1924 1948 usually not heard	May have had former Ch. S.O.M.	++	Usually 25-40
Group III	May have 100% decrease at any frequency	Usually 30 and 5 are heard	++ for 30 and 51	May or (may not) be present	+ or -	Usually elderly though occasionally in early twenties

Hearing improved and the improvement was lost later in 39 per cent.

Hearing was not improved in 7 per cent.

Hearing became worse in 3 per cent.

The degree of improvement is not specified nor is the final hearing level attained by the patient mentioned.

An interim report (patient operated upon less than 2 years previously) on the author's last 450 cases in the past 18 months under the previously mentioned groupings is as follows:

Group 1: Hearing was improved to the practical level and maintained in 86 per cent.

Group 2: Hearing was improved to the practical level in 33 per cent.

Group 3: In 3 cases no improvement was noted. In the latter series the author has not had a case in which the fistula has completely closed as judged by the fistula sign on probing.

The author emphasizes the importance of detailed follow through records of the operative technique together with standardized audiometric records to all surgeons actively engaged in the fenestration operation.

EUGENE L. DERLACKI, M.D.

NOSE AND SINUSES

Orbital Complications Resulting from Lesions of the Sinuses. AVIUM T. SMITH and JAMES T. SPENCER. *Ann. Otol. Rhinol.*, 1948, 57, 5.

The authors present 22 cases illustrating infections mucocoeles epidermoid cysts, and osteomas of the paranasal sinuses responsible for complications of the orbit. The intimate anatomical relationship between the sinuses and the orbit allows for ready involvement of the orbital contents by inflammatory and other lesions of the sinuses.

The diagnostic problem involved in the orbital complications depends upon a consideration of the symptomatology as follows:

1. The symptoms of inflammatory changes in the orbit such as (a) inflammatory edema of the eyelids (b) subperiosteal abscess a collection of pus between the bony wall and the periorbital, (c) orbital abscess (d) orbital cellulitis and (e) cavernous sinus thrombosis of the anterior or orbital type.

2. The symptoms of disturbances from mechanical causes due to encroachment upon the capacity of the orbit by mucocoeles, pyoceles chronic hyperplastic sinusitis cysts and neoplasms and manifested by displacement and disturbance in the mobility of the globe injury to the optic nerve, changes in refraction and disturbance in the drainage of tears.

3. The orbital apex or sphenoid fissure syndrome a syndrome consisting of ptosis complete ophthalmoplegia impaired vision and pain corresponding to the ophthalmic division of the fifth nerve which is caused by affection of the vessels and nerves which pass through the superior orbital fissure and the optic foramen.

The authors found in their study that difficulty and delay in diagnosis arose because (1) the sinus

infection was not apparent from symptoms or rhinologic examination (2) a noninflammatory lesion was obscured by inflammatory reaction (3) in spite of a history of sinus infection, the focus was elsewhere and (4) lesions of the sinuses such as mucocoeles cysts, or osteomas gave no nasal symptoms and encroached on the orbit so gradually that eye symptoms were not manifest until the involvement became marked.

The authors believe that roentgen examination was the greatest single aid in the diagnosis but it must be correlated with the clinical evidence.

As for treatment, inflammatory conditions causing orbital infections are most efficaciously treated with penicillin in adequate dosage given parenterally which largely obviates the previously practiced customary procedures. As for the lesions which cause disturbances by mechanical means the authors advocate surgical incision and drainage through the sinuses into the nose in cases of mucocoele pyocoele and hyperplastic lesions or surgical removal of neoplastic lesions such as osteomas, followed by the establishment of adequate nasal drainage.

In illustrating the problems of diagnosis and therapy the authors reviewed the case histories of (1) 6 cases of the inflammatory group (2) 3 cases of mucocoele (3) 1 case of epidermoid cyst of the frontal bone, and (4) 2 cases of osteoma of the frontal and ethmoid sinuses.

NOSE AND SINUSES

Orbital Complications Resulting from Lesions of the Sinuses. **AUSTIN T. SMITH and JAMES T. SPENCER.** *Ann. Otol. Rhinol.*, 1948, 57: 5

The authors present 15 cases illustrating infections mucocoeles epidermoid cysts and osteomas of the paranasal sinuses responsible for complications of the orbit. The intimate anatomical relationship between the sinuses and the orbit allows for ready involvement of the orbital contents by inflammatory and other lesions of the sinuses.

The diagnostic problem involved in the orbital complications depends upon a consideration of the symptomatology as follows:

1 The symptoms of inflammatory changes in the orbit such as (a) inflammatory edema of the eyelids, (b) subperiosteal abscess—a collection of pus between the bony wall and the periorbita, (c) orbital abscess (d) orbital cellulitis and (e) cavernous sinus thrombosis of the anterior or orbital type.

2 The symptoms of disturbances from mechanical causes due to encroachment upon the capacity of the orbit by mucocoeles, pyococles, chronic hyperplastic sinusitis, cysts and neoplasms, and manifested by displacement and disturbance in the mobility of the globe, injury to the optic nerve, changes in refraction and disturbance in the drainage of tears.

3 The orbital apex or sphenoid fissure syndrome, a syndrome consisting of ptosis, complete ophthalmoplegia, impaired vision, and pain corresponding to the ophthalmic division of the fifth nerve which is caused by affection of the vessels and nerves which pass through the superior orbital fissure and the optic foramen.

The authors found in their study that difficulty and delay in diagnosis arose because (1) the sinus

infection was not apparent from symptoms or rhinologic examination (2) a noninflammatory lesion was obscured by inflammatory reaction (3) in spite of a history of sinus infection, the focus was elsewhere and (4) lesions of the sinuses such as mucocoeles, cysts, or osteomas gave no nasal symptoms and encroached on the orbit so gradually that eye symptoms were not manifest until the involvement became marked.

The authors believe that roentgen examination was the greatest single aid in the diagnosis but it must be correlated with the clinical evidence.

As for treatment, inflammatory conditions causing orbital infections are most efficaciously treated with penicillin in adequate dosage given parenterally which largely obviates the previously practiced customary procedures. As for the lesions which cause disturbances by mechanical means the authors advocate surgical incision and drainage through the sinuses into the nose in cases of mucocoele pyococle and hyperplastic lesions or surgical removal of neoplastic lesions such as osteomas, followed by the establishment of adequate nasal drainage.

In illustrating the problems of diagnosis and therapy the authors reviewed the case histories of (1) 6 cases of the inflammatory group (2) 3 cases of mucocoele (3) 1 case of epidermoid cyst of the frontal bone, and (4) 5 cases of osteoma of the frontal and ethmoid sinuses. **EVONKE L. DEBLACKI, M.D.**

MOUTH

Oral Conditions with a Background of Systemic Disease. **KURT H. THOMA, DANIEL J. HOLLAND, JR., HOWARD W. WOODBURY, JARREL G. BURROW, and EDWARD L. SLEPKE.** *Oral Surg. M. Path.*, 1948, 1: 2.

This article concerns the report of 2 cases of oral disease which represent very dramatic examples of the importance of co-operation between the dental, medical, and surgical services for proper diagnosis and treatment of diseases the first symptoms of which may occur within the oral cavity. The neglect of a complete physical examination in such cases may cause very embarrassing results.

The first case was that of tumor of the maxilla associated with hypoparathyroidism. This case was that of a 62-year-old farmer who was referred to the dental clinic for treatment of a firm nontender, asymptomatic swelling of the left side of the face of 3 weeks' duration. This tumor involved the anterior portion of the left alveolar process and caused the left cheek to bulge. It had increased progressively for 3 weeks. The patient was referred by the dental clinic to the laboratory for blood studies after a biopsy of the lesion which came back as a giant-cell epulis.

The presumptive diagnosis of hypoparathyroidism was made at this time from the blood studies. Surgical intervention was discouraged and the patient was referred to the medical service of the hospital for further study. At that time the complete medical

history revealed that 4 months prior to admission the patient had noticed swelling of the right maxilla anteriorly, and 3 months previously he had consulted a local physician, who had excised the mass and removed a tooth root. After that, all his teeth were removed. Four weeks previously the patient had a similar swelling of the left maxilla anteriorly and he again consulted his physician, who believed the swelling to be similar to that on the other side and incised it obtaining a bloody mucous material. The completion of the operation was deferred because of the size of the mass. The patient was then referred to the dental clinic.

During the past 4 months the patient had also noticed excessive fatigue, extreme weakness, vomiting polydipsia and polyuria. His condition had become progressively worse. Physical examination disclosed bilateral firm nontender soft tissue mass in the antero maxilla. This was associated with a firm nodular swelling believed to be localized in the left side of the lower neck, probably within the thyroid. The remainder of the physical examination was negative. X-ray examination revealed cystic degeneration of the maxilla, granular appearance of the skull, and other bony decalcifications consistent with a diagnosis of osteitis fibrosa cystica.

It was agreed that surgical exploration of the parathyroids with presumptive diagnosis of parathyroid adenoma was indicated. Because of the poor physical condition the operation had to be deferred temporarily but it was done finally and bore out the clinical impression a large cystic parathyroid adenoma was extirpated. Closer exploration was not possible because of the condition of the patient. Postoperatively the patient's course was good except for a kidney complication which was treated by sulfadiazine. He also had several thromboses of the deep veins. However some time after he had recovered from the complications he stated that he had not felt so well for years.

This is one example of a case in which local excision of a tumor should not be done unless a complete physical examination and other studies are carried out. It is felt that such studies are not done often enough.

The second case mentioned in this article was a thrombocytopenic purpura associated with bleeding from the gingiva. First a very brief description of the etiology of the platelets in the clotting mechanism of the blood is given. The patient was admitted to the hospital on June 6, 1937 with the chief complaint of back pain and loss of weight. Examination was essentially negative, and a diagnosis of osteitis condensans illi was made. Laboratory findings on the initial admission were given. The patient returned home following instructions, but she began to have continuous, rather profuse bleeding from the gums. She also developed prolonged abnormal profuse menstrual bleeding.

On admission again on July 5, 1937 a diagnosis of purpura was made. This was confirmed by studies as well as physical examination.

A detailed account of the examination and laboratory tests is included in the report. The oral examination showed profuse bleeding from the gums, which did not respond to any local treatment. On July 9, 1937 a splenectomy was performed. On the first postoperative days the bleeding diminished and 4 times stopped completely. However, after the third postoperative day she began to bleed again and her condition progressively became worse in spite of blood transfusions and other supportive treatment she died on August 9, 1937. The autopsy revealed typical pictures of thrombocytopenic purpura.

The second case shows the possibility of a generalized disease with only local symptoms when first seen. The authors intimate that a patient with any type of bleeding that does not quickly resolve with local treatment should have a very complete examination for systemic disease.

The reports of these 2 cases include photographs of the lesions in question some photomicrographs, and a detailed description of the laboratory work done on these patients. WILLIAM A. ARROCK, M.D.

Gelatin Sponge in the Obliteration of Cavities Resulting from the Excision of Cysts and Tumors of the Jaw. KURT H. THOMA and EDWARD L. SULLIVAN. *Oral Surg. & Path.*, 1938, 24.

The authors briefly discuss the difficulties encountered in the obliteration of large cavities left by the enucleation of cysts of the jaw. The need of packings and the contamination from the mouth are all contributing factors to the breakdown of blood clots which fill the cavities following operation. The problem is not great in small cavities resulting from these cysts but in large ones the complications are of importance.

The aim in the treatment of large cysts of the jaw is always to remove the entire cystic epithelium and its contents with the exception of the involved roots and dentigerous cysts where normal eruption is likely to take place. If at operation the teeth in this condition are not interfered with, their normal eruption will take place. The authors state that the Parnis operation has its disadvantages because of the postoperative difficulties of taking care of the patient and the fact that usually a depression marks the site of the former cavity. They briefly report the method of space obliteration that has been worked out in various ways by other workers.

Synthetic bone paste has some advantages, particularly in small cavities which, however usually need no filling material. The difficulties encountered in filling large cavities with bone paste are given.

The authors give a brief description of the use of fibrin foam and gelfoam in filling such large cavities following operation on cysts of the jaw. They briefly give the histological picture concerning the absorption of this filling material and the absorption of bone formation. They state that gelatin sponge in such large cystic

cavities is probably much the same as that when the sponge is transplanted into soft tissues.

The authors state that before inserting the fibrin foam or gelfoam into the wound it should be soaked in a solution to make it more pliable and more readily adaptable to the cavity. It will soak in either normal saline solution in which no infection is present or in a thrombin solution with or without penicillin according to whether or not there is considerable bleeding and if or not infection is present. The use of it when the cavity is not exposed to oral bacteria presents no problem but in the authors experience it has caused very little trouble even if the oral contents has gotten into the wound.

The authors then report in some detail the history, examination and procedures carried out in 11 cases of large cystic cavities of the jaw in which gelfoam or fibrin foam was used to pack the cavities following the operation.

WILLIAM A. ARBROO, M.D.

Plastic Surgical Repair of Facial Paralysis. PAUL W. GREILEY. *Arch Surg* 1948 56 132

This article is a brief general discussion of the present day status of surgery for facial paralysis. The selection of the patient for surgery, the optimum time for operation and the desirability of neurosurgical consultation are discussed.

Primary nerve suture or nerve graft when sufficient substance has been lost should be done whenever possible. When such procedure is impossible resort must be had to measures which will support the paralyzed side. Antogenous fascia lata strips may be used purely as support. When combined with muscular attachments some activation may be obtained. Muscle pedicled flaps utilizing temporal muscle for the corners of the mouth and the eyelids lend animation but not necessarily support and are best used in conjunction with fascial support. Nerve substitution and use of foreign body material such as tantalum are not recommended.

EARL H. KLANOWE, M.D.

Surgical Correction of Developmental Deformities of the Mandible. REED O. DINGMAN. *Plast Reconstr Surg*, 1948 5 124

The first record of the use of a surgical procedure for correction of malrelation of the jaws dates back to 1848. It has been only during the past 50 years however that much interest has been shown in the surgical correction of prognathic deformities of the mandible. When one considers the great number of operations proposed for correction of this deformity and also the various operations in use today it is obvious that there is lack of uniformity of thought in regard to this problem. It is also evident that there is no one operation without some undesirable features.

Osteotomy is accomplished by transverse division of the ramus of the mandible, and shifting of the body of the bone backwards where it is held in position during the course of healing.

It is today the most popular of the operative procedures because it is simple to execute, avoids the

possibility of injury to the inferior alveolar nerve, it does not entail sacrifice of useful bone, nor does it damage the mandibular arch or teeth. The operation also can be done without contamination with the oral cavity. There are, however, numerous disadvantages, very few of which have been given adequate mention in the literature.

Although excellent results have been obtained in the correction of prognathic deformity by the method of osteotomy, there are many disadvantages to the procedure, and the possibility of failure is great. (1) possibility of lack of control of upper or proximal segment due to muscular action with separation of fragments and nonunion. (2) nonunion is possible. (3) osteotomy through the neck of the condyle may result in destruction of function of both temporomandibular joints. (4) osteotomy through the neck by the blind passage of a gigli saw has the disadvantage of inability to control the proximal fragment with the possibility of injury to seventh nerve and internal maxillary artery and the possibility of throwing the muscles of mastication out of normal alignment. (5) a transverse cut too close to the sigmoid notch offers the possibility of separation of the coronoid from the condyloid process.

The alternate choice of site of operation to that of cutting through the ramus of the mandible is section through the body of the mandible or osteotomy. In osteotomy a previously measured section of bone is removed from the body of the mandible.

The removal of a section of bone from the body of the mandible has numerous advantages. The operative site is more accessible and the fragments can be more easily controlled and held in position with very great accuracy by means of dental splints fitted to the teeth or to the alveolar ridges of the mandible. In sectioning through the body of the mandible there is no interference with the muscles of mastication and there is no possibility of an open bite relationship developing after the anterior fragment has been placed accurately in position. The chief objections to this procedure are the sacrifice of functional teeth in many instances and destruction of normal bone at the site of osteotomy.

The advantages of osteotomy are: (1) osteotomy affords the greatest possibility of avoiding the mandibular nerve and associated structures. (2) it is easy to execute. (3) it avoids the extraction of normal teeth and the sacrifice of useful bony structure and (4) also avoids the possibility of oral contamination.

The author advocates a two stage method of osteotomy, a modification of the method introduced by Harsha in 1912, by which a section of bone is removed from the body of the mandible without interfering with the inferior alveolar nerve and associated structures. The procedure consists of removal of a section of bone from the body of the mandible without cutting the inferior alveolar nerve or compound ing the wound intraorally.

The first stage is a relatively minor procedure and the patient is treated under local anesthesia as an

out-patient. If the area is edentulous, this consists of making an incision along the crest of the alveolar ridge and gingival margins of the adjacent teeth, and elevating the mucoperiosteum from the buccal and lingual surfaces in the immediate vicinity. If a tooth is removed at the same time the mucoperiosteum is elevated from the buccal and lingual plates opposite the area of extraction. Using a bone drill, the bone is cut downward and transversely across the alveolar ridge. In order to avoid injury to the inferior alveolar nerve, a safe distance is maintained between the depth of the bone incision and the nerve. The bone is not removed at this time. The soft tissue is returned to position and carefully sutured in place over the ridge.

During the second stage, incisions are made bilaterally parallel and 1 cm. below the inferior border of the mandible in the selected area. Careful dissection should be done to avoid the mandibular branch of the facial nerve. Through this incision the lower border of the body of the bone is exposed. By carefully retracting the periosteum a slight amount, medially and laterally the cuts in the bone from the previous intraoral stage are readily identified. By the use of bone drills, these cuts are extended through the cortical plate of bone down to the lower border of the mandible. A horizontal cut through the cortical plate on the lateral surface about 1 cm. above the inferior border and between the two vertical cuts permits the insertion of a small chisel. A twisting motion fractures off the lower border of the bone, exposing the nerve. Great care is exercised in order to avoid the mandibular nerve, which is carefully exposed by removal of the surrounding medullary bone. After identification of the nerve and before the bone is completely excised, holes are drilled with a small bone drill from the buccal to the lingual nerve just above the inferior border of the bone on both sides of the osteotomy site. These small holes provide pathways for passage of 22 gauge stainless steel or tantalum wire, which is used to approximate the bone fragments. The medullary portion of the bone is then countersunk or hollowed out in the immediate vicinity of the nerve to permit a resting place for the excess of nerve when the bone fragments are approximated. After excision of the bone up to the nerve, it is quite simple to remove the entire block of bone above the nerve without getting into the oral cavity. The bone should be wired securely to prevent slipping or upward riding of the posterior fragment due to action of the closing muscles of mastication. The wires are twisted tightly and cut short.

Retraction deformities in which the mandibular teeth are within the normal limits of occlusion with the maxillary teeth may be satisfactorily corrected by bone or cartilage implants to the anterior surface of the mandible. In marked retraction deformities with malocclusion, implants of this kind fall short of producing the ideal result.

A procedure designed to advance the bone in order to improve the occlusal relationships as well as

the contour of the chin seems advisable in certain deformities.

The author has employed a two stage operative procedure for correction of retraction deformities of the mandible in 3 cases. The operation is done through the body of the mandible and is accomplished in such a way that the inferior alveolar nerve and its associated structures are not destroyed. The operation being done through the body of the mandible offers the distinct advantage (over operations done through the ramus) of noninterference with the muscles of mastication. LOUIS T. BYARS, M.D.

Osteomyelitis of the Jaw. KURT H. THOMA, DANIEL J. HOLLAND JR., HOWARD W. WOOD, URY JABIEL, G. BURROW and EDWARD L. SLEEPER. *Oral Surg. M. Path.* 1948, 76

The authors state that the treatment of bone infection that was developed by them has continued to give good results. This treatment consists in combining the use of antibiotics appropriate for the infecting organism with adequate surgery to remove dead and infected bone, followed by careful débridement of the area and saucerization of the bone defect. The antibiotics are given intramuscularly but are also supplemented by local instillation directly into the involved areas.

The authors give in some detail the case histories of several cases in which this technique was carried out with satisfactory results. These cases were (1) acute osteomyelitis of the mandible associated with infected wen, (2) subacute osteomyelitis of the ascending ramus, (3) osteomyelitis of the mandible following tooth extraction, (4) chronic osteomyelitis of the mandible following accident, and (5) irradiation necrosis of the maxilla.

WILLIAM A. ABRAMS, M.D.

NECK

Thyroiditis. GEORGE CHILL, JR., *Ann. Surg.* 1948, 127: 640.

This study concerned with the 3 main clinical types of thyroiditis, consists of 47 cases of subacute thyroiditis, 14 cases of struma lymphomatosa, and 11 cases of Riedel's struma. Each of these conditions is a distinct entity of unknown etiology and probably unrelated to the other two. All of them occur predominantly in the female and as a rule, after the fourth decade.

Subacute thyroiditis is much more common than the others. It may be the consequence of a virus infection, and is considered the same disease as pseudotuberculous or giant-cell thyroiditis. It is characterized by a diffuse subacute inflammation with numerous foreign-body giant cells, probably related to the colloid in the degenerating follicles. A firm, symmetrical enlargement of the gland occurs but this is seldom pronounced.

In contrast to the other types, the onset is usually sudden, pain and thyroid tenderness is marked and there is evidence of a systemic toxic reaction but

true hyperthyroidism does not appear. Easily recognized subacute thyroiditis tends to subside spontaneously without significant alteration of the thyroid function. Irradiation brings about a prompt and dramatic response and obviates the need for thyroidectomy. Thionitril may be beneficial.

Struma lymphomatosa also known as Hashimoto's thyroiditis is a progressive disease which appears to be related to deficiency disorders. Histologically one notes an extensive acidophilic element by fibrous and notably lymphoid tissue containing well developed germinal centers. The process is diffuse and while the entire gland increases markedly in size its shape becomes somewhat asymmetrical.

Struma lymphomatosa is insidious in onset and usually asymptomatic except for the hypothyroidism or at least a peculiar hypometabolism which does not always respond specifically to glandular extract. Occasionally when the trachea is encircled symptoms of obstruction appear. In the rare case radiation may prove beneficial. A very conservative resection of both lobes is recommended when the disease is recognized at operation as the morbidity is high following radical resection.

Riedel's struma, also known as woody or ligulous thyroiditis is the least common of the 3 conditions. The typically concentric laminations of fibrous tissue surrounding degenerating adenomas suggest that some change in the adenoma may be responsible for the reaction. In contrast to the other conditions the inflammatory process is limited as a rule to one lobe and is productive of a very large bulky stone-confining of the capsule to infiltrate and involve the trachea and adjacent structures. This process is slow but progressive and may be indistinguishable from advanced carcinoma preoperatively.

It commences without pain tenderness or systemic symptoms. However pressure symptoms often with tracheal obstruction, are present in over one-half of the cases. Irradiation is of little or no value and surgery is apt to be difficult. It is unwise, move the entire lobe. Removal of the core containing the adenoma when possible appears to relieve the symptoms and promote subsidence of the fibrous proliferation.

DAVID H. LYNN M.D.

A Contribution to the Knowledge of the Frequency of Thyrotoxicosis in Finland during the Years 1935-1946. O. BISTRÖM. *Acta med scand.*, 1948, 130: 109.

The author examined the records of the Helsingfors City Hospital and the General Hospital of Helsinki for the years 1935 to 1946, inclusive. Townspeople were treated in the former hospital and countryside people in the latter. Since both institutions are associated with the University the diagnoses were accepted as reliable.

Of 2114 thyrotoxic patients only 241 (11 per cent) were males. Most of the patients were in the fourth decade but there were 2 in the first decade and 15 in the eighth or a later decade. In 1935 there was a total of 155 cases of this disease in the two hospitals.

In the succeeding years ending with 1946 the numbers were 217, 203, 188, 255 (1939), 206, 234, 126, 162, 99, 174, and 185. The peak years were 1936 (217 cases), 1939 (255 cases), and 1941 (234 cases). The low years were 1942 (126 cases) and 1944 (99 cases). The curve representing these figures was very much the same as that in the graphs for (a) the number of thyrotoxic patients per 1,000 total patients in the hospitals for each year, (b) the severe cases and (c) the incidence of exophthalmos. No great difference was noted between the curves for the townspeople and the rural people.

The author correlates the graphs with various factors particularly with change in psychological tension and with food supply. He believes that the most likely factor influencing incidence and severity is the food supply. At least, the smallest number of cases occurred during the period of greatest scarcity of food and the greatest number at times of greatest availability of foods especially protein and fat.

CLINTON H. THIRTEEN, M.D.

Subglottic Cylindroma with Special Reference to its Clinical Course. DAVID LEE and HERBERT L. CASE. *Laryngoscope*, 1948, 58: 338.

The authors emphasize that every case of clinical asthma should be studied by endoscopy for tracheobronchial pathology. Primary malignant disease of the trachea is rare. Cylindromas are tumors in which hyaline strands or balls are interspersed with strands of flattened cells. They are generally benign but may metastasize and they are probably epithelial in origin arising from the glands or surface epithelium of the mouth and nasopharynx.

A case is reported of a 52 year-old white male, whose complaints were a choking sensation, bloody expectoration, dyspnea, and dysphagia of a years duration. He was in great distress with a wheezing respiration. A previous diagnosis of asthma had been made. Laryngoscopy revealed a subglottic mass from which biopsy material was obtained. The pathological report described only chronic inflammation. The patient's condition improved but symptoms recurred in a month at which time surgery consisting in tracheotomy and removal of the subglottic mass with fulguration of its base was performed. The pathologic diagnosis was cylindroma. The tracheotomy tube was removed on the third postoperative day and the patient made an uneventful recovery and obtained complete relief of all symptoms.

There is diversity of opinion as to whether surgery or radiotherapy should be advised in the treatment of these tumors. In this case surgery proved a safe and remedial procedure.

S. LLOYD TITZELMAN M.D.

The Use of Contact Therapy in the Treatment of Carcinoma of the Larynx. BAUCK PROCTOR, JAMES E. LOFFSTROM, and CARL E. NURNBERGER. *Laryngoscope* 1946, 56, 5.

Since April, 1946 the authors have treated 9 patients with carcinoma of the larynx by the technique of laryngofissure and contact x ray therapy. Eight of the patients were of the type usually treated by laryngectomy or massive external irradiation, but they either had refused such irradiation or had complications which were contraindications for the more radical treatment. During the 22 months of the study, only one recurrence occurred (at 4.5 months). The dose varied from 5,000 to 12,000 roentgens.

An elaborate description of the radiation technique with dosage charts is given in this 18 page report. CLINTON H. TAYLOR, M.D.

Extirpation en Bloc of the Larynx and of the Lateral Cervical Nodes on One Side (Asportazione in blocco della laringe dei gangli laterocervicali mono-laterali). VITTORINO PRICOLA. *Chirurgia* 947.

45

The author describes his procedure in the surgical treatment of cancer of the larynx and its metastases. He removes the larynx and the cervical lymph nodes on one side en bloc.

A basal preanesthetic is given followed by local infiltration of both the superficial and deep tissues the larynx and the cervical plexus.

A U^l incision is made through the skin and subcutaneous tissue extending from the mastoid on one side, along the posterior border of the sternocleidomastoid muscle above the clavicle and to the opposite mastoid. After the posterior margin of the sternocleidomastoid is freed and the sheath of the trachea is opened the sternocleidomastoid muscle is sectioned at its insertion to expose the scalenus muscles. All adipose tissue is removed from the supraclavicular space. The omohyoid the transverse cervical vessels and some rami of the cervical plexus are sectioned after the internal jugular vein is ligated

at the base of the skull and at the clavicle. Attention is paid to the facial and hypoglossal nerves when the posterior belly of the digastric and stylohyoid muscles is detached. The spinal nerve accompanying the internal jugular vein was sectioned, as were the superior laryngeal nerve and vessels. The posterior border of the thyroid cartilage is freed and the hyoid bone is separated from the suprahyoid musculature always from the back to the front. The posterior margin of the thyroid gland is liberated from the thyroid cartilage without opening of the perichondrium but the constrictor fibers are separated.

When the larynx has been isolated by this procedure an endotracheal and an endolaryngeal anesthetic block is effected. The trachea is sectioned below the cricoid cartilage the dissection starting from below and the pharynx is thereby opened as far as the base of the tongue. The larynx is excised en masse with the hyoid bone and with the nodes of the jugulocervical chain on one side of the neck. The pharyngeal wound is closed with two layers of continuous catgut No. 00, with care to avoid entering the mucosa with the suture. The author then sutures the trachea to the skin and places a gauze drain on the side of the removed internal jugular vein and a rubber drain on the opposite side.

In 3 patients in whom the cancer had metastasized to the cervical nodes on both sides the operation was done in two stages. Extirpation of the larynx en bloc with the lymph nodes and internal jugular vein was done first on one side of the neck, followed after one month by the second operation during which the lymph nodes and the internal jugular vein on the opposite side of the neck were removed. The histological examination showed metastases in both sets of nodes. After 3 years of observation no ill effects were seen in these patients.

Fifteen patients have been operated upon by this technique without a mortality or complication, either operative or postoperative. No fistulas formed.

ARTHUR F. CIRIELLA, M.D.

SURGERY OF THE NERVOUS SYSTEM

SPINAL CORD AND ITS COVERINGS

Paraplegia in Cervical Spine Injuries. ROLAND BARNES. *J Bone Surg.*, 1948 30B 234.

One of the most puzzling features of injuries of the cervical spine is the lack of correlation between the degree of vertebral displacement and the severity of the spinal-cord lesion.¹ The author is convinced that spinal-cord injury can occur in the absence of any vertebral dislocation. Twenty two cervical spine injuries are classified into flexion and hyperextension types. The former group is further subdivided into (1) anterior dislocation (2) acute retropulsion of an intervertebral disc, and (3) crush fractures of a vertebral body. The hyperextension types are (1) posterior dislocation and (2) injury to an arthritic spine.

Cord damage in the nine cervical dislocations was due to a combination of pressure on the dorsal surface by dislocated neural arches and simultaneous compression of the ventral surface of the cord by a retropulsed disc. Skeletal traction was the treatment of choice.

Three cases of acute retropulsion of the intervertebral disc are presented, only one of which was actually visualized at operation; the 2 other patients were merely treated by skeletal traction and recovered partially from their paralysis. Because of the narrowed intervertebral disc space and the absence of x ray evidence of bony injury, retropulsion of the disc was inferred. Treatment varied with the case.

If the disc was not regarded as degenerated before injury, traction was used to restore the disc height. If paralysis was incomplete and the Queckenstedt test was normal, the cord was regarded as being under severe compression, and a trial of skeletal traction was justified. If there was no recovery from paraplegia within a few days laminectomy was considered, even though the Queckenstedt test was normal.

In 4 cases there was a marked crush fracture of the vertebrae with destruction of the cord of varying severity. In one of these cases there was compression of the ventral surface of the cord by an extruded disc. Treatment of these injuries was similar to that used for spinal-cord compression due to a retropulsed disc.

There were 6 cases of hyperextension injury to arthritic spines. All of the patients were over 50 years of age and had moderate or severe changes of the spine without roentgenographic evidence of recent vertebral injury. The mechanism of this type of injury is discussed. With hyperextension of the cervical spine there is rupture of the anterior common ligament, avulsion of a small bit of bone from the anterior margin of the upper vertebra, and a tear through the disc. The latter does not extend into the canal. No resistance is offered to further hyperex-

tension, and wider separation of the bodies occurs. After the initial trauma, normal alignment of the vertebrae is restored by spasm of the neck muscles and there is no apparent distortion noted in the roentgenogram of the spine.

Minor displacements of spurs on the vertebrae may cause concussion of the cord. The author has likewise postulated that a traction injury to the cord may occur since neurological levels corresponding to several segments above the point where hyperextension has occurred are found. Experimental work performed by the author does not tend to substantiate this theory, but he is not satisfied completely with the methods used. There is no indication for the use of traction in these cases. Neither is immobilization in plaster necessary; this is uncomfortable and often dangerous in the older patients usually found with this condition. Treatment is best accomplished by gentle flexion of the cervical spine produced by placing a pillow under the head.

RICHARD C. SCHWEIDER, M D

Paraplegia in Hyperextension Cervical Injuries ALEXANDER R. TAYLOR and WILLIAM BLACKWOOD *J Bone Surg.* 1948, 30B 245

Damage to the cervical part of the spinal cord with paraplegia may occur without x ray evidence of dislocation or injury of the vertebrae. Several mechanisms have been postulated. One is that the massive prolapse of a disc may cause pressure on the cord, however the authors state that this lesion can usually be recognized in the roentgenograms by a slight narrowing of the intervertebral space. Another suggested etiology is a hyperflexion dislocation which causes paraplegia with spontaneous reduction. But the authors believe that a flexion of this severity would be sufficient to cause in addition a crushing of the vertebrae or dislocation of their facets and thus be detectable roentgenographically.

Forced hyperextension of the spine without x ray evidence of displacement is proposed in this article as the usual mechanism of the type of injury described. Two cases are presented to illustrate this point. It is thought that this factor was overlooked for so long because surgeons have been indoctrinated with the belief that the anterior ligaments are so strong they will not rupture, and the assumption that if there is severe hyperextension of the cervical spine the atlas and axis will fracture through the arches at the base of the odontoid.

The differential diagnosis lies mainly between acute prolapse of the intervertebral disc and hyperextension injury with immediate reduction. Very minor changes in the roentgenogram such as narrowing of the intervertebral disc space or the suspicion of wedging of the vertebrae suggest a ruptured disc. Myelography should demonstrate a disc of sufficient size to cause damage to the cord. On the

The Use of Contact Therapy in the Treatment of Carcinoma of the Larynx. HADCK PROCTOR, JAMES E. LOVETROM, and CA. L. NURNBERGER. *Laryngoscope* 94:5, 58-59

Extirpation en Bloc of the Larynx and of the Lateral Cervical Nodes on One Side (Asportazione in blocco della laringe dei gangli laterocervicali mono-laterali.) VITTORIO PICCOLI. *Chirurgia* 94:7-8-45

The author describes his procedure in the surgical treatment of cancer of the larynx and its metastases. He removes the larynx, and the cervical lymph nodes on one side en bloc.

A basal preanesthetic is given followed by local infiltration of both the superficial and deep tissues, the larynx and the cervical plexus.

A U incision is made through the skin and subcutaneous tissue extending from the mastoid on one side along the posterior border of the sternocleidomastoid muscle, above the clavicle and to the opposite mastoid. After the posterior margin of the sternocleidomastoid is freed and the sheath of the trapezius is opened the sternocleidomastoid muscle is sectioned at its insertion to expose the scalenus muscles. All adipose tissue is removed from the supraclavicular space. The omohyoid, the transverse cervical vessels and some rami of the cervical plexus are sectioned after the internal jugular vein is ligated

at the base of the skull and at the clavicle. Attention is paid to the facial and hypoglossal nerves when the posterior belly of the digastric and stylohyoid muscles is detached. The spinal nerve accompanying the internal jugular vein was sectioned as were the superior laryngeal nerve and vessels. The posterior border of the thyroid cartilage is freed and the hyoid bone is separated from the suprahyoid musculature always from the back to the front. The posterior margin of the thyroid gland is liberated from the thyroid cartilage without opening of the perichondrium, but the constrictor fibers are separated.

When the larynx has been isolated by this procedure an endotracheal and an endolaryngeal anesthetic block is effected. The trachea is sectioned below the cricoid cartilage, the dissection starting from below and the pharynx is thereby opened as far as the base of the tongue. The larynx is excised en masse with the hyoid bone and with the nodes of the jugulocarotid chain on one side of the neck. The pharyngeal wound is closed with two layers of continuous catgut No. 00, with care to avoid entering the mucosa with the suture. The author then sutures the trachea to the skin and places a gauze drain on the side of the removed internal jugular vein and rubber drain on the opposite side.

In 3 patients in whom the cancer had metastasized to the cervical nodes on both sides, the operation was done in two stages. Extirpation of the larynx en bloc with the lymph nodes and internal jugular vein was done first on one side of the neck, followed after one month by the second operation during which the lymph nodes and the internal jugular vein on the opposite side of the neck were removed. The histological examination showed metastases in both sets of nodes. After 3 years of observation no ill effects were seen in these patients.

Fifteen patients have been operated upon by this technique without a mortality or complication either operative or postoperative. No fistulas formed.

VITTORIO F. PICCOLI, M.D.

separation of the cases in which the less extensive procedure alone was performed. The operative mortality was 10 per cent.

The patients in this series were operated upon during the period between 1933 and 1941. The ages varied from 14 years to 57 years of age. The greater number of patients however were in the fifth decade. Sixty-two per cent of the patients were males. The three most common complaints were headache, visual disturbances, and dyspnea.

A 5 year study of the 143 patients who survived revealed that 31 of the patients or 21.6 per cent, survived for at least 5 years; 23 patients or 17 per cent lived from 5 to 12 years after surgery. In comparison with similar series of patients who had had medical treatment only, especially the Keth Wagner Barker series and the Page series, these results may be considered excellent. A study of 25 cases by Flaxman however revealed a 5 year survival rate of 34 per cent, under medical management. A re-evaluation of 21 patients who survived for 5 years or more revealed that 4 were maintaining a completely normal blood pressure. In 7 patients the blood pressure was reduced by at least 80 mm. or more systolic, and 25 mm. diastolic pressure. In 6 cases there was a significant reduction of 48 mm. systolic and 15 mm. diastolic pressure, whereas there was no significant change in 5 cases. In 20 patients with preoperative headaches, 10 had complete relief and 9 were definitely improved. Of 14 patients with visual disturbances, all but 1 had noted definite improvement.

The preoperative complaints of anginal seizures, weight loss, and muscle pain were apparently very ominous for none of the patients with these complaints had survived 5 years. Eleven out of the 13 patients without evidence of cardiac involvement prior to operation were still living 5 to 12 years after surgery. Two of 16 patients with congestive heart failure before surgery survived for a period of 5 years. Previous episodes of cerebrovascular disease were apparently of little importance, for 6 of the patients who had had previous cerebral accidents were still living and had had no recurrence.

Recklinghausen's Neurofibromatosis Associated with Intrathoracic Meningocele. C. STUART WELCH, ALICE ERTIMER, and PAUL L. HECHT. *N. England J. M.*, 1942, 338, 622.

The authors report a case of neurofibromatosis in a patient who showed roentgenological evidence of an intrathoracic tumor with marked erosion of the lateral and anterior surfaces of the fifth, sixth, and seventh thoracic vertebrae. Examination revealed a kyphoscoliosis in the midthoracic region but no neurological signs. A transthoracic operation showed the tumor to be a meningocele.

The authors discuss 3 previously reported cases of intrathoracic meningocele, 2 of which occurred in patients with Recklinghausen's neurofibromatosis.

They suggest myelographic studies as an aid in differential diagnosis.

GEORGE PERRY, M.D.

Sacroccocygeal Chordoma. FERNANDO GENTIL and BRADLEY L. COLBY. *Ann. Surg.*, 1948, 127, 432.

This study is based on 7 cases of sacroccocygeal chordoma observed and treated at the Memorial Hospital, New York, during the period from 1930 to 1943, and 128 instances previously reported.

Chordoma is a specific tumor arising from remnants of the primitive notochord. It is characterized by slow inexorable growth, a tendency to invade and destroy bone by direct extension, local recurrence after surgical excision, and slight or negligible regression following radiation. Occasionally distant lymph node and visceral metastases occur.

Virchow first called attention to chordoma in 1856 when he described small tumorlike cartilaginous masses at the spheno-occipital synchondrosis and termed the condition echordosis physaliphora. The term chordoma was introduced 2 years later by Müller. Ribbert in 1894 first established the correct nature of this neoplasm and described 5 cases of his own.

Although chordomas may occur at any age, they are usually encountered during the fifth decade, with a range of from 3 months to 78 years. They are slightly more common in males, a difference difficult to evaluate.

The bulk of evidence indicates that these tumors arise from primitive fibroblastic cells of the notochord. Of all the types of chordoma, 60 per cent were sacroccocygeal, 30 per cent spheno-occipital, and 10 per cent were evenly distributed in the cervical, thoracic, and lumbar regions. The predilection of chordoma for the sacroccocygeal area has never been satisfactorily explained.

Grossly these tumors are bulky, encapsulated, lobulated, cystic, and purplish red. Cut sections reveal areas of homogeneous and translucent tissue with irregular cavities filled with abundant thin mucin. The microscopic appearance is characteristic and consists of large cells resembling bladder epithelium (physaliferous cells) which contain intracellular and extracellular mucin. These cells are arranged in cords, lobules, or a solid epithelial pattern. Sometimes a syncytial vacuolated arrangement is present. In the malignant types mitotic figures, cellular pleomorphism, hyperchromatic nuclei, and multinucleated giant cells are found. The tumor is of low grade malignancy, widespread metastases being found in about 10 per cent of the cases.

Symptoms are due to location of the growth and are dependent on expansion and destruction of the adjacent bone. The average duration of symptoms is 20 months before the patient consults a physician. Pain is the earliest and most frequent symptom causing the complaint of anal and rectal distress. Fecal and urinary disturbances may occur as the tumor invades these regions. With involvement of the posterior nerve roots, sensory disturbances in the lower portions of the body commence. In far advanced cases the picture is that of intractable pain.

ther hand, an older patient with a kyphotic deformity or a patient with a history of injury to the face or forehead suggests a hyperextension injury. Tearing of a small chip of bone from the anterior portion of the vertebral body suggests rupture of the anterior ligament and, if myelography is negative, the diagnosis of hyperextension injury is clinched. The authors are skeptical of the occurrence of "recoil" of the disc with spontaneous reduction in hyperflexion injuries. They believe that the annulus and the posterior longitudinal ligaments will not stretch sufficiently to cause contusion to the cord without actual rupture.

The diagnosis of hyperextension injuries is important because, if the customary treatment of extension is applied to this type of injury, reallocation of the spine may occur with narrowing of the spinal canal. The patient with this type of injury should be treated in a shell or immobilized between sandbags with his head in a neutral or slightly flexed position.

PERIPHERAL NERVES

Pressure at the Cervicobrachial Junction. E. D. TELFORD and S. MOTTENHEAD. *J Bone Surg* 94A, 30B 249.

The causes of pressure on the neurovascular bundle at the cervicobrachial junction are many and varied. In a careful study the authors present 199 cases in which the patients were operated upon for symptoms referable to pressure on this region. There were 109 uncomplicated cases in which the symptoms in the upper extremity were classified as being due to pressure by fibrous bands from abnormal disposition of the scalene muscles, by cancellous osteomas, deformed thoracic outlets due to pressure of the clavicle on the first rib and lastly by cervical ribs. Seventy of these cases, or 66 per cent, were due to cervical ribs, while in 5 cases, or 4.7 per cent, there was no obvious cause found. Seventeen patients had complications which overshadowed the customary symptoms. Of these 15 had extensive arterial thromboses and well developed cervical ribs. The 8 other patients suffered from hyperhidrosis which was severe enough to interfere with their work and one of these also had a cervical rib.

Three controversial points concerning pressure on the neurovascular bundle are discussed. In reviewing the scalenus anterior syndrome, the authors point out that in their experience there are many people who do not get relief from anterior scalenotomy. Those who benefit from the operation fall into a group in which the action of the anterior scalene muscle is passive and mechanical, i.e., fibrous bands actually do occur wide insertions of the muscle on the cervical rib are present, or overlapping with the scalenus medius occurs. The active action of the scalenus anterior muscle attributed to spasm disease, or injury is discounted completely. The authors do not feel that there is justification for the diagnosis of "scalenus anterior syndrome" and opera-

tion directed at sectioning of the anterior scalene muscle alone.

As to the costoclavicular syndrome, conclusions were formed on the basis of extensive clinical studies on 120 medical students and more than 50 careful cadaver dissections. If there is a normal relationship between the clavicle and the first rib there can be no compression of the neurovascular bundle against the rib. However if this space is narrowed either by a large cervical or abnormal first thoracic rib, then any retraction and abduction of the shoulder may lead to pressure symptoms. Depression of the clavicle is the normal individual cause none of these symptoms because the further the shoulder is depressed the wider is the costoclavicular span.

Arterial thrombosis, a serious complication of cervical rib, is carefully reviewed. The authors believe that thrombosis may occur as a result of pressure which causes constant irritation of the sympathetic fibers of the lowest trunk of the brachial plexus. Prolonged arterial spasm occurs secondarily. However, in some of the cases a gross abnormality of the vessel wall which could not be attributed to this cause was noted at operation. This change was explained by paralysis of the vasomotor nerves which degenerate as a result of repeated contractions. Secondary dilatation and stretching of the denervated middle coat of the vessel extends distal to the site of the injury just as far as the point at which the next nerve relay enters. No doubt, after prolonged trauma or stretching of this aneurysmal dilatation, thrombosis takes place.

In conclusion, it was emphasized that operations for the relief of symptoms due to pressure on the neurovascular bundle of the upper extremity should not be carried out with the thought of doing one pre-conceived procedure, but should be done in the nature of an exploration with wide enough exposure for adequate investigation of the entire region.

RICHARD C. SCHNEIDER, M.D.

The Problem of Malignant Hypertension and Its Treatment by Sympathetic Resection. MAX M. PEET and EARL M. TIERRO. *Ann. Int. M.* 94B, 25 755.

Despite an occasional report in the medical literature listing malignant hypertension as a contraindication to sympathectomy the authors refute this statement and present a series of 143 patients with malignant hypertension who have been treated by Peet's supradiaphragmatic sympathectomy. The diagnosis of malignant hypertension is based upon the following criteria: (1) a rapidly progressive deteriorating clinical course of recent onset; (2) severe neuroretinitis with a definite papilledema of one diopter or more; (3) high diastolic blood pressure and (4) evidences of constitutional involvement.

The operative procedure was a one-stage resection of all of the splanchnic nerves and also of the eighth through the twelfth thoracic sympathetic ganglia. Although in the earlier operations only the three lower dorsal ganglia were removed, there was no

SURGERY OF THE THORAX

TRACHEA LUNGS, AND PLEURA

Cancer of the Lung. Interval and Late Results of Operation in Relation to Topography and Gross Pathology HAROLD NEUFELD and ARTHUR H. AUFSER, *J Thorac Surg.*, 1948, 17: 297

Fifty two consecutive patients surviving operation for lung cancer during the 10 year period from 1935 to 1945 at the Mount Sinai Hospital New York, are divided into three topographic groups and show the following

Group I (21 cases) consisted of the main and branch bronchus cancers. Twenty patients were treated by pneumonectomy 7 (33%) now survive.

Group II (18 cases) consisted of circumscribed cancers which appear encapsulated grossly. Six patients were treated by pneumonectomy with survival of 50 per cent and 12 were treated by lobectomy with survival of 33 per cent.

Group III (13 cases) consisted of peripherally invasive cancers. Twelve patients were treated by lobectomy with survival of 23 per cent.

The authors state that (1) topographic classification should be used as a basis for operability, (2) lobectomy has its indications in the surgery of pulmonary carcinoma and (3) prognosis based on microscopic features cannot be made with any assurance.

The data presented do not permit an analysis of these conclusions. FRANK B. QUINN M.D.

HEART AND PERICARDIUM

Coarctation and Aneurysm of the Aorta. HARRIS B
SHUMACKER, JR. *Ann. Surg.*, 1948 127 655

The author reports the case of an 8½ year-old boy with coarctation of the aorta associated with an aortic aneurysm distal to the stenosis which was treated successfully by excision of the involved segment and repair by end to-end suture of the divided aorta.

The child was hospitalized because of a cardiac murmur recurrent attacks of otitis media, and a bacteremia with blood cultures positive for the pneumococcus type VII. He presented findings typical of coarctation of the aorta, and a barium swallow revealed an indentation in the esophagus in the region of the aortic arch. He was thought possibly to have bacterial aortitis and was treated with penicillin and sulfadiazine with prompt subsidence of the signs and symptoms of bacteremia and infection. The patient was then operated upon.

Operation was carried out through the bed of the fifth rib posteriorly. A coarctation of the aorta was found in the usual location and, in addition a sacular aneurysm about twice the diameter of the aorta itself the mouth of which arose immediately distal to the coarctation on the right lateral wall of

Fig 1 (Shumacker) Diagrammatic sketch of the condition found at operation. The condition following excision of the aneurysm and coarcted portion of the aorta is shown in the insert.

the aorta (Fig 1) was noted. The aneurysm and coarcted segment were excised between special clamps as a single specimen, and end-to-end suture of the divided aorta was accomplished by means of a continuous everting mattress suture of number 5 Deknatel. The patient made an uneventful recovery and when seen 8 months after operation was very well and had a brachial blood pressure of 106/70 as compared with a preoperative reading of 140/70. Pulsations in the vessels of the lower extremities were normal but had been absent preoperatively.

The aneurysmal sac was lined with platelets and fibrin but contained no demonstrable organisms, a microscopic picture not incompatible with infected vegetations rendered sterile by chemotherapy. The exact origin of the aneurysm could not be determined. Possible factors in general are atheromatous degeneration of the elastic tissue of the aortic wall, traction by the ligamentum arteriosum, previous bacterial aortitis with mycotic aneurysm development, and dilatation due to collateral return through aortic intercostals. Dilatation and aneurysm of the aorta may occur either proximal or distal to a coarctation, as pointed out by Abbott, and by Reifstein, Levine and Gross in their respective autopsy studies in cases of coarctation of the aorta. Approximately 20 per cent of the deaths in coarctation occur from rupture of the aorta and another 20 per cent occur as a result of bacterial endocarditis or aortitis.

As far as can be ascertained the case reported here is the only recorded one in which an aortic aneurysm was excised and end-to-end suture was done although Alexander and Byron reported excision of a thoracic aortic aneurysm with ligation of the aortic ends. However numerous cases of excision of coarcted aortic segments with end-to-end suture have been reported by Gross Crafoord and Nylin and others.

paraplegia and incontinence. The sacrum is particularly liable to destruction.

The most constant physical finding is a mass, the exact location depending on the direction of tumor growth. The hollow of the sacrum should always be carefully palpated. Widespread metastases occur, though rarely to the lungs, liver and peripheral lymph nodes.

Sacral chordoma is strongly suggested by a bulky mass externally or in the hollow of the sacrum together with roentgenologic evidence of adjacent bony destruction. Additional evidence is involvement of the pelvic viscera and the absence of overlying skin or subcutaneous tissue invasion.

Differential diagnosis includes chondrosarcoma of the sacrum, tuberculosis of the sacrum, tumors of the female pelvic organs, tumors of the spinal cord, tumors of the sacral soft parts, sacrococcygeal teratoma, and carcinoma of the rectum.

The roentgenographic findings as concluded in the extensive study of Hsieh and Hsieh are expansion, rarefaction or destruction, trabeculation, and calcification.

The final diagnosis is always dependent on histological examination, and aspiration biopsy is recommended. A correct diagnosis was made by this method in 6 of the 7 new cases reported here.

Since these tumors show slight if any response to radiation therapy and complete extirpation of the tumor is not feasible, management is chiefly for partial control and palliation. Spinothalamie tractotomy is recommended for the control of pain. A surgical procedure consisting of colostomy, ureteroenterostomy and tumor excision has been considered, but appears unduly radical at present. Repeated surgical excisions are advised.

Since sacral chordomas are characteristically slow growing, numerous recurrences follow repeated ex-

cisions with massive invasion of the pelvis in late stages of the disease. Occasionally a single surgical extirpation results in control. Among the 38 reported cases, metastases occurred in 15, the most frequent sites being the regional and peripheral lymph nodes, lungs, liver and skin, respectively. The spheno-occipital type in striking contrast, almost never metastasizes.

C. FREDERICK KITTEL, M.D.

Some Observations on the Neurogenic Bladder
WILLIAM F. WHITMORE, JR., AND LUIS AL. ISALEL
N. York State J. M. 943, 48-50.

Based on their observations of 90 patients with spinal cord injury seen in a Veterans' Administration Hospital, the authors classified the "neurogenic bladder" in each instance according to the following grouping: the numbers of patients of each type being given.

1. Normal, 2
2. Uninhibited reflex, 5
3. Reflex, normal, 48, and reflex, hypertonic, 7
4. Autonomous, 38
5. Atonic, 0.

The detailed definition of each type is given.

Ten per cent of the patients had cervical lesions; 61.1 per cent thoracic lesions and 28.9, cauda equina lesions. Both complete and incomplete cord lesions were included.

Among other observations, it was noted that 45.6 per cent of the patients developed satisfactory bladder function, while in 54.4 per cent it was considered unsatisfactory. There was a very gratifying result in general from the use of transurethral resection of the vesical neck. The authors also noted that in their patients suprapubic cystostomy is deleterious to the ultimate development of satisfactory bladder function.

JOHN MARTIN, M.D.

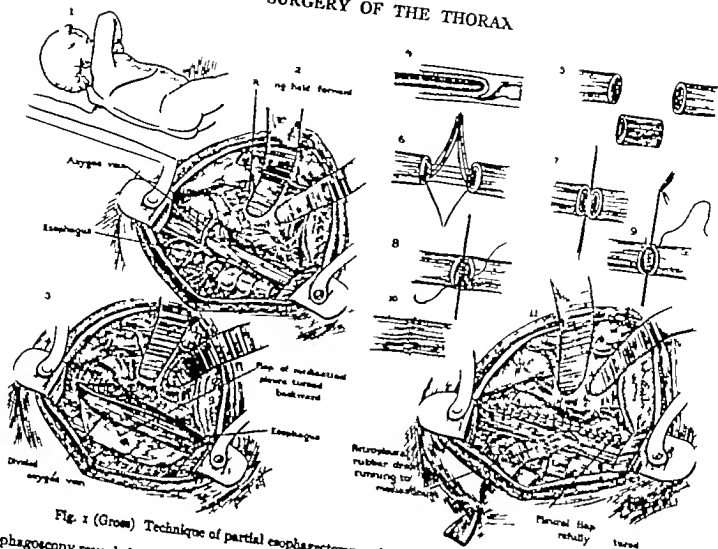

Fig. 1 (Gross) Technique of partial esophagectomy and end-to-end esophageal reconstruction.

esophagotomy revealed obstruction of the esophagus in its middle portion. Because of marked weight loss and inability to swallow a gastrostomy was done. After a satisfactory state of nutrition was obtained, the esophagus was exposed through a right transpleural approach and a 3 cm. segment of it excised. A primary end-to-end anastomosis was done. Mediastinal and pleural drains were inserted. The postoperative course was uneventful and, when last seen the patient could swallow without any difficulty.

C. FARMER KITTLE, M.D.

Congenital Esophageal Atresia and Tracheoesophageal Fistula. CLAYTON G. LYON and STANLEY G. JOHNSON. *J. Thorac. Surg.*, 1948 17 161

Four hundred and sixty-eight cases of esophageal atresia, with or without tracheoesophageal fistula, have been reported. The anomaly has been classified under five main types:

1. The upper esophageal segment terminates in a blind pouch in the upper third, and the lower esophageal segment is represented by the presence of a similar blind pouch there being no communication with the trachea.
2. The upper esophageal segment communicates with the trachea and the lower segment is a blind pouch.

3. The upper segment terminates blindly and the lower segment of the esophagus communicates with the trachea above the carina.

4. Like type 3 but the lower segment communicates with the trachea at the carina or with the right or left main stem bronchi.

5. Both segments communicate with the trachea.

The diagnosis is suggested by increased oral secretions, attacks of cyanosis or the regurgitation of feedings. Confirmation is obtained by passage of a small catheter into the esophagus which meets an obstruction in the upper third or fails to enter the stomach. The patient is fluoroscoped while 0.5 or 1 c.c. of lipiodol is introduced through the catheter without its tracheal communication. The inferior level of the upper esophageal segment is elevated during deglutition. After the examination, the lipiodol should be aspirated as it is easily regurgitated and enters the tracheobronchial tree. Roentgenograms of the chest and abdomen are valuable in determining the condition of the lung fields in the presence of other anomalies and the presence of gas in the gastrointestinal tract. Gas in the gastrointestinal tract is usually indicative of a fistula.

Four cases are reported in which a transpleural approach with the patient under intratracheal anes-

The feasibility of excision of aortic aneurysms is based on the location of the aneurysm and the collateral circulation which is present. It is unlikely that aneurysms of the ascending aorta, aortic arch, or the first portion of the abdominal aorta supplying important visceral vessels can be excised successfully whereas short segments of the descending thoracic aorta and the distal abdominal aorta may possibly be resected and continuity restored provided methods of increasing the collateral circulation become available. The use of vein transplants to bridge aortic defects is suggested. **JAMES E. THOMPSON M.D.**

Primary Vascular Tumors of the Pericardium.
MORRIS GREENBERG and ALFRED ARONST. Am. Heart J. 943, 35 6 3.

Primary pericardial tumors are distinctly rare and are usually either sarcomas or lipomas.

Vascular pericardial tumors are even more rare. Only 5 of the reported cases can be accepted as true neoplasms. Three of these were cavernous angiomas and 2 malignant angioendotheliomas. The remainder were, in reality, examples either of vascularization in organizing blood clots or of prominent vascular channel formation in granulation tissue.

The authors report 3 cases of true primary vascular pericardial tumors. Case 1 was a small (1 cm.) benign cavernous angioma found incidentally in the sulcus between the right and left ventricles in a patient dying of peritonitis following operation for adenocarcinoma of the rectum. Case 2 was an invasive cellular angioendothelioma in a 37 year old male dying of cardiac insufficiency produced by the tumor.

No specific clinical picture for tumors of the pericardium has yet been evolved because signs and symptoms vary with the location and extent of the tumor and with the presence of hemorrhage its amount, and rapidity of occurrence. If a previously healthy person shows, without known cause a rapid evolution of symptoms of decompensation and an enlarged cardiac shadow a pericardial tumor should be considered. **FRANK B. QUINN M.D.**

ESOPHAGUS AND MEDIASTINUM

Treatment of Short Stricture of the Esophagus by Partial Esophagectomy and End To-End Esophageal Reconstruction. **ROBERT E. GROOM, Surg., 943, 5 735**

For many years the standard treatment of congenital and chemical burn esophageal strictures has been dilatation although recently there have been numerous techniques devised to establish some type of antithoracic esophagus. More recently transthoracic esophagegastrostomy has been employed. Primary end-to-end esophageal anastomosis has been regarded as technically impossible in the past, but during the last 2 years numerous successful attempts have been recorded. This method seems preferable to the more radical transthoracic esophagegastrostomy since fairly normal anatomic reconstruction is effect-

ed and since it does not interfere with normal functioning of the stomach.

Certain technical aspects of esophageal resection and anastomosis for stricture deserve consideration.

1. The retropleural approach is advocated in children. This insures a reasonable degree of expansion of the lung and eliminates contamination of the pleural cavity during operation which gives a maximum protection should there be any leakage during the esophageal anastomosis. It also provides a direct route for external drainage if suppuration or esophageal leakage should occur postoperatively. In older subjects a transpleural route is preferable.

2. Mobilization of the esophagus is accomplished more easily on the right than on the left side. A right sided incision will not permit the stomach to be drawn up into the thoracic cavity but unless it can be definitely determined before operation that an esophagegastrostomy will not be necessary the left approach should be used.

3. Many different types of incision have been advocated, but in general a long intercostal one is best provided it is located exactly at the level of the lesion. In older patients in whom the costal cage is less yielding it may be necessary to divide several ribs posteriorly.

4. Since reconstruction of the protective bulkhead between the mediastinum and pleural cavity is important, great care must be taken to preserve the parietal pleura covering the esophagus. The longitudinal opening of this layer should be made anterior to the esophagus so that a broad flap can be raised and sutured over it after anastomosis has been performed.

5. The esophagus must be widely mobilized to accomplish its anastomosis without undue tension. Although its poor vascularity has been commented on extensively in the past, the author states that the entire intrathoracic portion may be freed without subsequent damage if this is necessary for resection and reconstruction.

6. Inspection of the esophagus externally may give little clue to the location of the stenotic lesion. For accurate localization a catheter is inserted by the anesthetist and pushed to the constricted region.

7. The esophageal anastomosis is sutured in two layers with No. 5-0 silk the outer layer including the muscularis and submucosa, the inner the mucosa. Crushing of the phrenic nerve does not appreciably facilitate the operation.

8. A soft rubber drain is inserted into the mediastinum through a stab wound in the back to provide for any postoperative mediastinal suppuration.

9. A rubber catheter is placed into the pleural cavity routinely to allow suction and insure evacuation of the pleural cavity.

10. The establishment of a gastrostomy is advisable to allow for adequate nutrition and to permit healing of the esophageal anastomosis during the early postoperative period.

The case of a 21-month-old boy with intermittent vomiting since birth is presented. Barium studies and

operation an esophageal pouch was found and a fistula between the distal esophagus and right main bronchus was ligated. The gap in the esophagus was too great for direct anastomosis. The second operation was a gastrostomy. At the third operation the superior mediastinum was entered and the blind end of the esophagus freed and brought out through the chest wall. It was opened a days later. The construction of the esophagus was then done in stages forming a skin lined tube. The procedure consisted of forming two separate skin lined flaps one attached to the esophagostomy opening and one to the gastrostomy and later attaching these together. Feeding by mouth was begun right away. A constriction was found at the gastrostomy opening which was corrected by operation.

From a pediatrician's viewpoint, the operation of choice when possible, is primary anastomosis. The multiple stage operation with or without a jejunal segment or a free jejunal transplant is a formidable amount of surgery and has psychological implications for the patient. The multiple stage operations require extensive hospitalization with exposure to infection and a tremendous utilization of hospital services.

With all these facts in mind the possibility presents itself of the advisability of performing a primary anastomosis with a thoracic stomach when the segments cannot otherwise be approximated with safety. This operation has been attempted in infants by Singleton and might be considered in suitable cases.

LOUIS T. BYARS, M.D.

Esophageal Hiatal Herniae of the Short Esophagus: Types: Etiologic and Therapeutic Considerations. ARTHUR M. OLSEN AND STUART W. HARRINGTON. *J. Thorac. Surg.*, 1948 17 189.

A study was made of 220 patients with short esophagus and a partial thoracic stomach seen at the Mayo Clinic. On the basis of this review the following conclusions were drawn and observations made.

True congenital short esophagus is rare (4 per cent of the cases in the authors series). In an overwhelming majority of the cases shortening of the esophagus was acquired in the later years of the patient's life.

Basic anatomic factors in the development of hiatal hernia are congenital enlargement of the esophageal hiatus of the diaphragm and atrophy or weakness of the diaphragmaticoesophageal membrane.

Shortening of the esophagus develops as a result of peptic ulceration of the esophagus. Peptic ulceration of the esophagus may be the result of (1) excessive or prolonged vomiting or (2) incompetence of the physiologic sphincter at the cardia, when it occurs in association with hiatal hernia or with reflex spasm of the lower part of the esophagus. Reflex spasm of the esophagus is the result of stimulation of the vagus nerve and may be produced by a variety of digestive disorders.

Dysphagia is the most common symptom associated with the short esophagus. In early stages spasm may be the cause of dysphagia. However, organic stenosis of the lower part of the esophagus develops in most cases.

Hiatal hernia of the short esophagus type is not favorable for surgical treatment. When dysphagia is present dilatation may be carried out by passing sounds over a previously swallowed thread. Medical measures are directed against further ulceration of the lower part of the esophagus.

Because the treatment of the short esophagus type of hernia is radically different from that of the usual hiatal hernia it is important that an accurate diagnosis be made. Careful roentgenoscopic studies are necessary and esophagoscopy examination is frequently required if hiatal hernia of the short esophagus type are to be differentiated from hiatal hernias with an esophagus of normal length.

Preoperative, Operative, and Postoperative Care in Esophageal Resections. HERBERT C. MAIER. *Surgery* 1948 23 884.

Recent advances in the reduction of morbidity and mortality following radical resection of the esophagus for carcinoma have been due to better preoperative preparation of the patient, improvements in anesthesiology, chemotherapy, a better understanding of the physiological alterations during and following operation, improved surgical technique, and better postoperative care.

Preoperative preparation of the patient. Because of the obstructive changes usually present in varying degrees, the esophagus should be cleansed above the tumor. All retained material and secretion should be aspirated and daily lavage of the esophagus instituted. Care should be taken that no aspiration into the lungs occurs. The importance of good mouth hygiene is emphasized. It is preferable to correct nutritional deficiencies if possible through feeding by mouth together with supplementary parenteral injections, rather than to perform a preliminary jejunostomy. Gastrostomy is to be avoided in any case in which the stomach requires mobilization at the time of the esophageal resection. The correction of the hypoproteinemia as well as the other nutritional deficiencies may require a week or two. A fluid diet or if feasible a soft diet high in proteins, carbohydrates, and vitamins is given. In some cases preoperative blood or plasma transfusions and amgen are indicated. Vitamin C deficiency should be corrected by a daily dose of from 200 to 1,000 mgm. of ascorbic acid parenterally. Transfusions are given if the hemoglobin is less than 80 per cent after dehydration is corrected.

The preoperative work up should also include an evaluation of the cardiac and renal status. Preoperative digitalization may be indicated. Any clinical or laboratory evidence suggesting coronary sclerosis requires constant effort to avoid anoxia at all times during and following operation. The presence of emphysematous lungs is important since

thorax was employed. The operative procedure is given in detail.
SAMUEL KARR, M.D.

A New Method of Restoring Continuity of the Alimentary Canal in Cases of Congenital Atresia of the Esophagus with Tracheoesophageal Fistula not Treated by Immediate Primary Anastomosis. RICHARD H. SWEET. *Ann. Surg.* 94, 7 757

It has been shown by Ladd and others that in many suitable cases of congenital atresia of the esophagus with tracheoesophageal fistula it is possible to close the fistula and perform an immediate primary esophageal anastomosis. In other cases in which primary anastomosis is impossible, cervical esophageotomy and gastrostomy are established as lifesaving measures. In the latter types of patients it is possible to create an external esophagus by various multiple-stage time-consuming maneuvers, the results of which on the whole have been discouraging. The author describes a new method whereby continuity of the alimentary tract can be restored in this group of patients with previous cervical esophageotomy and gastrostomy by carrying out an intracervical esophagogastric anastomosis after pulling the stomach up through the chest.

The operation is performed in one stage with three steps. The first step is carried out through a left-sided eighth-rib transthoracic approach. The entire stomach to the level of the pylorus is mobilized by cutting the gastroduodenal and gastrohepatic ligaments and all vessels except the right gastric and right gastroepiploic, with care to avoid injury to the vascular arcades. The rudimentary distal stump of the esophagus is removed and the gastrostomy opening is closed. The fundus of the stomach is pulled up into the chest posterior to the hilum of the lung and temporarily anchored at the apex. The chest is then closed and the patient turned onto his back. In the second step a vertical incision is made in the left side of the neck, the esophagotomy is mobilized and the lower portions of the clavicle and first rib are resected. The apex of the thorax is thus entered and the stomach pulled out into the neck. Esophagogastric anastomosis is then carried out with three layers of interrupted silk sutures, as described by the author previously. The final step is the closure of the abdominal-wall portion of the gastrostomy.

The case of a 21 month-old infant treated successfully by this method is reported in detail. At the latest follow-up the patient was eating a diet normal for his age, was gaining weight slowly and had no obvious physiologic disturbances resulting from the displacement of his stomach through the chest into his neck.

The method was also employed successfully in a 56-year-old man to resect a carcinoma of the esophagus situated behind the manubrium of the sternum, a level too low for a Wooley procedure and too high for transthoracic esophagectomy with high intrathoracic esophagogastric anastomosis.

JAMES E. THOMPSON, M.D.

Construction of Skin Tube Esophagus following Surgical Treatment of Tracheoesophageal Fistula. ROBERT H. IVEY, H. R. HAWTHORNE, and JOSEPH A. RITTER. *Plast. Reconstr. Surg.* 94, 3 73

Various procedures have been proposed for reconstruction of the esophagus following resection for stricture due to caustic burns, malignant disease, or congenital anomalies. Where the gap is sufficiently small, direct anastomosis of the free ends may be possible. In other cases an epithelium-lined tube of transplanted tissue must be used to restore the continuity. This has been accomplished intrathoracically by carrying a segment of jejunum or a tubed portion of the stomach up to meet the upper stump of the esophagus. Extrathoracic methods comprise the formation of an epithelium-lined tube beneath the skin of the anterior chest wall, connected above with the opening in the neck of the upper stump of the esophagus and with the gastrostomy below.

In 1917 Esser made an anterior thoracic esophagus by tunnelling beneath the skin of the chest and inserting a large rubber tube covered with Talersch skin grafts. The ends of this epithelium lined tube were later connected with the esophageal opening above and the stomach below.

In 1942 Davis and Stafford reported a case of stenosis of the esophagus following lye burns. After the preliminary operations of gastrostomy and for formation of a fistula of the upper stump of the esophagus in the neck the extrathoracic esophagus was constructed by the formation of a tube lined with inverted skin extending from the upper fistula down toward the gastrostomy opening, a tubed pedicle flap from the side of the body being used for covering. The lower end of this skin-lined tube was later joined to the stomach by a segment of jejunum.

Longmire and Ravitch employed, for the lining of the tube, a loop of jejunum ultimately completely isolated from its mesenteric blood supply. In several stages with successive severance of the vessels supplying it, the segment of jejunum was implanted in the skin tube, so that it finally was completely cut off from its original blood supply. The jejunum-lined skin tube was then transferred to the anterior chest to serve as a channel between the upper part of the esophagus and the stomach.

Ladd reports an extensive experience with esophageal atresia and tracheoesophageal fistula. Of 34 patients, 11 are still living after various operations. In 5 of these direct anastomosis was possible, in 2, the anterior thoracic esophagus was completed, and in a third patient it was in process of construction the remaining 6 patients were all doing well and awaiting construction of an anterior thoracic esophagus.

In a more recent paper published in January 1947 Ladd and Swenson discuss the subject further. They recommend attempted direct anastomosis if the gap is not more than 2 cm.

In the case reported, the technique described by Ladd was followed as closely as possible. At the first

time of esophagoscopy routine bronchoscopy has been done on 4 occasions the tumor was found to invade the left stem bronchus or trachea which obviated the necessity for exploration.

The preoperative preparation the operative technique and the postoperative complications are discussed in detail.

SAMUEL KAHN, M.D.

Mesothelial Mediastinal Cysts (Pericardial Cysts)

Differential Diagnosis of Shadows Continuous with the Anterior Inferior Mediastinum. GEORGE COOPER, JR., VINCENT W. ARCHER, and JOHN R. MAFF. *South M J* 1948 41 285

A circumscribed homogeneous shadow projecting from the anterior inferior mediastinum and continuous with the shadows of the diaphragm and anterior chest wall is most apt to represent a mesothelial mediastinal cyst.

A number of other conditions benign and malignant cannot be ruled out without biopsy.

Demonstration of such shadows is indication for exploratory thoracotomy. JOHN J. MALONEY, M.D.

MISCELLANEOUS

Spontaneous Mediastinal Emphysema and Spontaneous Pneumothorax; a Report of 20 Cases. HELEN A. DICKIE. *Ann. Int. M* 1948, 38 618.

That spontaneous mediastinal emphysema is not a rare condition is indicated by the rapidly increasing number of case reports in the literature. Quite commonly there is an associated spontaneous pneumothorax. Over a 4 year period 20 cases of pneumothorax, pneumothorax or a combination of the two were diagnosed among students seen at the University of Wisconsin Student Health Service. In 6 cases pneumothorax alone was present, 7 individuals showed mediastinal emphysema without pneumothorax and in 7 patients both conditions were present.

The mechanism of the production of a spontaneous pneumomediastinum is obscure and the usual explanation is that air from a ruptured alveolus in the lung has caused dissection along the perivascular sheath to the mediastinum. The experimental work of Maclellan with cats showed the associated pneumothorax to be caused by a rupture of the mediastinal pleura with the resultant escape of air into the pleural space. The frequent association of the two states as seen clinically suggests that this same mechanism may occur in the majority of spontaneous pneumothoraces seen in otherwise healthy individuals. The reason for the distention and rupture of the alveolus is not known there is usually no history to suggest increased intrabronchial tension preceding the onset. In many of the cases the student was sitting in class or at study when the rather dramatic symptomatology suddenly ensued.

Characteristically the onset of spontaneous pneumomediastinum is sudden with pain of varying severity felt subinternally with radiation to the back, neck, shoulder or occasionally as in angina pectoris to

the little and ring fingers of the left hand. In about half of the cases peculiar noises over the precordium are audible to the patient. On examination a crunching sound which varies with the phase of respiration or with changes in position is heard over the precordium. Often this sound is similar to that of pericardial friction rub. Hyperresonance over the precordium is a constant finding.

In only 3 of her 14 cases could Dickie demonstrate mediastinal air by means of roentgenograms or the fluoroscope, even with repeated examinations in various positions. Unless the mediastinal air is large in amount or is localized there is insufficient contrast with the air-containing structures about the mediastinum to make it visible. This difficulty is further increased by the associated pneumothorax which is commonly on the left side.

Electrocardiograms show no constant pattern for mediastinal emphysema with or without pneumothorax, but are of value in excluding the more serious conditions, such as coronary occlusion or pericarditis, which have a similar syndrome.

The disease runs a benign course, and treatment in the main is purely symptomatic. Cough should be controlled but sulfonamides or antibiotics as prophylaxis against mediastinitis are not recommended. When the acute symptoms of mediastinal air have subsided the patient is treated on an ambulant status. Because of the alarming onset of the condition patients must be reassured that they have no serious cardiac or pulmonary pathology.

WAYNE F. CAMERON, M.D.

Congenital Diaphragmatic Hernia: Anatomic and Surgical Importance of the Left Triangular Ligament of the Liver. PHILIP THORAX. *Arch. Surg.* 1948, 56 238.

A not uncommon lesion in the newborn is diaphragmatic hernia. Morgagni (1769) was the first to give this subject serious consideration although Paré had reported 2 traumatic instances as early as 1610. Case reports now number in the thousands. The relative increase in frequency appears to be due to better diagnostic methods and the consideration by clinicians of its existence.

Since elements of the adult diaphragm are derived from several embryological sources, various defects are possible according to the location and extent of the developmental anomaly. The following classification is given:

1. Herniation through the posterolateral portions of the diaphragm along the embryonic pleuropertoneal canal (foramen of Bochdalek). This is the most common location. The left side is involved four times as frequently as the right.

2. Herniation through the esophageal hiatus due to lack in development of one or both diaphragmatic crura.

3. Herniation through the retrosternal area (foramen of Morgagni). This is a herniation through the region of the retrosternal attachments of the diaphragm and is the least common type.

slight changes in pulmonary expansion in the emphysematous individual may lead to respiratory insufficiency with resultant anoxia, which may in turn bring about cardiac complications. With recent advances in anesthesiology preoperative pneumothorax does not seem advisable for esophageal surgery. Preoperative penicillin therapy is usually begun from 24 to 48 hours prior to operation. Before operation, a Levin tube is introduced through the nose and placed in the esophagus so that the end of the tube is just above the site of obstruction.

Care of the patient during operation. The fundamental principles are (1) the avoidance of obstruction of the airway and adequate oxygenation throughout the operation (2) adequate blood and fluid replacement throughout operation (3) minimizing reflex disturbances in the operative field by the avoidance of unnecessary trauma (4) minimizing contamination of the operative field, (5) maintenance of an excellent blood supply and avoidance of tension at the site of anastomosis (6) periodic inflation of the lung during the intrapleural part of the operation, and (7) complete re-expansion of the lung as the pleural cavity is closed. In any case in which there is even a suspicion that the opposite pleural cavity may have been entered a roentgenogram of the chest is taken in the operating room at the conclusion of the operation and inspected at once. If this shows any appreciable degree of pneumothorax, aspiration of the air with a syringe fitted with a three way stopcock and connected to a manometer is indicated. Closed drainage is instituted on the side of the operation.

Postoperative care. In the experience of the author, hypoproteinemia has occurred following esophageal resection in spite of plasma transfusions, blood transfusions, antigen, or other protein derivatives administered parenterally. Perhaps the hypoproteinemia resulting from delayed feeding entails more leakage from the suture line than would occur if feeding were started early by mouth. Therefore in addition to giving plasma, blood transfusion and liberal doses of vitamin C postoperatively the author begins feeding by mouth within 1 or 2 days of operation. Repeated plasma protein determinations are important.

The length of time the drainage tube is left *in situ* depends upon (a) the completeness of pulmonary expansion (b) the thoroughness of evacuation of air and fluid from the pleural space, (c) whether the tube is still functioning or has been sealed off inside the thorax, and (d) whether the tube *in situ* would be a factor of safety should complications develop in the region of the anastomosis. It is obvious that the drainage must be kept airtight at least during the first week after operation if drainage has to be maintained for this long a period of time. When the tube is withdrawn, the withdrawal must be rapid, with immediate tying of the previously placed mattress or purse-string suture to close the opening.

The principles which must be observed to reduce postoperative cardiac complications are (1) avoidance of anoxia at all times, (2) avoidance of any in-

terference with pulmonary ventilation, (3) avoidance of any appreciable drop in the blood pressure (4) reduction of vasospastic factors as far as possible, (5) avoidance of an increased tendency toward intravascular clotting due to changes in the blood constituents and blood flow. Digitalis has an important place in the postoperative therapy.

The principles to observe in avoiding reduction of bronchial secretion are (1) proper nursing assistance with manual support of the area of incision during coughing, (2) proper use of sedation with avoidance of undue pain, and (3) the early use of intratracheal suction if voluntary cough is impossible or ineffective. If these measures are followed, bronchoscopy which is also an important therapeutic measure will be necessary only occasionally. Therapeutic bronchoscopic aspiration should be employed with no hesitation. Bedside roentgenograms should be taken frequently in the postoperative period if it is thought that they might give information of value in the diagnosis and management of pulmonary complications.

Whether or not it is advisable to introduce the Levine tube past the gastroesophageal anastomosis into the intrathoracic portion of the stomach at the time of operation is a moot point.

Oxygen therapy either through tent, nasal catheter or mask, should be given to every patient. Early ambulation should be encouraged as much as possible and leg exercises in bed can be performed until the patient is allowed up.

HAROLD LAUTMAN, M.D.

Surgical Management of Carcinoma of the Lower Two-Thirds of the Esophagus and Cardiac End of the Stomach. JOHN W. STENZEL. *J. Thorac. Surg.* 9:48, 7:143.

The experience with 72 operations on 71 patients with carcinoma of the esophagus, occurring at or below the arch of the aorta and of the cardiac end of the stomach is presented.

The youngest patient who had a successful resection was 52 years old, the oldest was 84. The general condition of the patient, especially the condition of the cardiovascular system is of more importance than the chronological age. Involvement of the cervical lymph nodes is relatively rare, except in lesions high in the esophagus. In lesions below the arch, the lymphatic drainage tends to the periesophageal and the subphrenic regions, and to the nodes in the region of the celiac axis and left gastric arteries.

Metastatic lesions in the lungs and pelvis should be carefully sought. Involvement of the liver is a late manifestation. The tendency for primary esophageal lesions to spread in the wall of the esophagus is known, so that a wide excision of the tumor should be made when possible.

Esophagoscopy with positive tissue biopsy is almost always possible in cases of cancer of the esophagus, and is frequently possible when the esophagus is involved by high gastric cancer. At the

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Floss-Silk Lattice Repair for Inguinal Hernia RODNEY MALNGOT *Lancet* Lond. 1948 1 861

The author has used a floss silk posterior lattice repair operation exclusively (Fig 1) on all patients with a direct inguinal hernia encountered during the past 10 years. The same procedure was adapted for large oblique hernias in which the internal ring and the floor of the inguinal canal had been unduly stretched or in which the muscular and fascial supports appeared to be weakened and atrophied, as well as for certain types of recurrent inguinal hernias, particularly in enfeebled patients.

The immediate and late results were classed as excellent. Among the last 100 cases sepsis developed in only 2 patients but on removal of the offending ligatures and with penicillin therapy healing was satisfactory. Sepsis most often occurred in obese patients in the aged and in patients who had had 2 or 3 or even more herniorrhaphies. Avoidance of supplementary operative procedures such as those for varicocele and hydrocele during operation on a hernia, as well as operation on only one side at a time has cut down complications.

STEPHEN A. ZITMAN M.D.

Fig 1 (Malngot) Floss-silk lattice repair for inguinal hernia.

Gastritis preoperative or postoperative is an important complication of gastric surgery

RICHARD J. BENNETT JR., M.D.

On Gastric Myoma and Fibroma. SAKARI TIMONEN *Ann. chir. gyn. fenn.*, 1948, 37 52

The author presents 3 cases of benign tumors of the stomach which were removed at operation. The first was a benign bleeding myoma, the second a fibroleiomyoma or stenosing type of myoma, and the third a fibroma showing no serious symptoms. These were all benign nonepithelial gastric tumors.

A reliable diagnosis was not made postoperatively in any of the cases, which is not unusual for these tumors. Histological diagnosis offers difficulties in determining the type of tumor and in ruling out malignancy. For these reasons, gastric resection is recommended as the proper surgical procedure.

STEPHEN A. ZITMAN M.D.

Carcinoma of the Stomach. CLAUDE E. WELCH and ARTHUR W. ALLEN *N. England J. M.*, 1948 238 383.

A study of all the patients with carcinoma of the stomach admitted to the Massachusetts General Hospital Boston during the 10 year period from 1937 to 1946 shows that the delay before treatment has remained unchanged, an average of 5 months. However the more aggressive attitude toward gastric ulcer has increased the recognition of early cancer of the stomach.

The introduction of a transthoracic approach and the wider use of total abdominal gastrectomy have increased the number of cases available for resection.

The mortality for gastric resections for cancer has dropped to a present level of 17 per cent for the entire series and to 11 per cent in the last 5 year period.

GASTROINTESTINAL TRACT

Observations on the Etiology of Postoperative Gastritis. EDDY D. PALMER. *Gastroenterology* 1948, 10. 671

It is suggested that gastritis is more important postoperatively than is an anastomotic ulcer. Vomiting, bleeding, weight loss and pain aggravated by food are the more important complaints.

The author's material consists of 24 cases. There was a rigid selection of cases with elimination of the cases which included any complicating factors. The patients included 1 woman and 1 negro. Their ages varied from 19 to 66 years. Four had a simple gastrotomy or gastrostomy, 1 had an esophagogastrotomy, 8 had gastrojejunostomies, and 11 had subtotal gastric resections. All of the patients were hospitalized for study. Complete work-ups were carried out and a rather rigid routine was adhered to. Six tables are presented in detail.

It was found that most postoperative chronic gastritis represents merely the continuation of preoperative gastritis, with or without surgical aggravation. Chronic gastritis which is due to surgery is of the superficial atrophic type. The secretion activity of the stomach plays little or no part in the postoperative development of gastritis. In cases in which there is rhythmic activity of the stomach gastritis may still develop.

Modern resection technique apparently did not prevent the development of postoperative gastritis.

Herniations through the aortic and vena caval openings have not been reported. A diaphragmatic hernia may or may not have a sac limiting its superior border.

Congenital diaphragmatic hernias produce symptoms manifested by the respiratory, circulatory and intestinal systems, according to the viscera interfered with and the severity of displacement. Any newborn who displays cyanosis, dyspnea, and vomiting or any combination of these should be suspected of having a diaphragmatic hernia. Symptoms vary greatly in degree from intermittent attacks of vomiting, cyanosis, respiratory difficulty and vague dyspepsia to constant distress with any of these.

Physical findings of a congenital diaphragmatic hernia are usually limited to increased pulse and respiratory rates although the affected side may be less mobile and there may be some dullness to percussion or tympany, according to the viscera present within the chest. The diagnosis is established by roentgenological examination of the chest. Although the viscera forming the hernia can usually be determined with ordinary x rays, a barium swallow is necessary in some instances.

The treatment of this condition is surgical. The earlier such patients can be operated on, the less distention and enlargement there will be of the intestinal viscera within the chest. Preoperative measures are designed for deflation of the alimentary tract, the establishment of proper hydration, and prophylactic chemotherapy. Although a trans-thoracic approach is best in adults, the abdominal

route is superior in infants. The author emphasizes the importance of the left triangular ligament of the liver. This is a bloodless fold of peritoneum, of which severance permits mobilization of the left lobe of the liver to the right with immediate visualization and adequate exposure of a hiatal hernia. Positive pressure anesthesia is essential. After the abdominal viscera have been reduced from the thoracic cavity, the hernial sac, if one is present, should be excised and sutured and the diaphragmatic defect repaired. Usually this is best accomplished by interrupted cotton sutures. Closure of the abdomen may be difficult, and interrupted through-and-through sutures are suggested rather than a closure by layers.

Postoperative care should include blood transfusion, oxygen therapy, early oral feeding, chemotherapy and frequent chest roentgenograms.

The case of a 7 weeks old female infant with congenital diaphragmatic hernia through the esophageal hiatus is presented. The herniation was due to non-development of the left crus of the diaphragm. The symptomatology was that of cyanosis, convulsive seizures and postprandial vomiting. Physical examination revealed moderate cyanosis, decreased expansion of the left side of the chest, and hyperresonance of the right chest with tympany in the lower portions of the left chest. The left border of the heart was at the right midclavicular line. Roentgenological findings diagnosed a diaphragmatic hernia. The child was operated on successfully with an uneventful postoperative period.

C. FRANKLIN KITTLE, M.D.

Pneumonitis was the most frequent complication. There appeared to be close correlation between the severity of malnutrition and the incidence of pneumonitis in these patients, in that 41 of the 47 patients gave evidence of extreme weight loss, anemia, and hypoproteinemia. Twelve of these 47 patients had congenital esophageal atresia with tracheoesophageal fistulas. This primary lesion may well have contributed to the incidence of pneumonitis.

The incidence of phlebotrombosis or thrombophlebitis and pulmonary embolism can be explained by the failure of the attending physician to look for or find evidence of venous thrombosis in the lower extremities.

A palliative gastrostomy in patients with inoperable malignant neoplasms or other hopelessly incurable lesions produces no significant extension of life and no demonstrable nutritional improvement.

Since neither life expectancy nor outstanding nutritional improvement is to be gained by palliative gastrostomy, the use of this procedure for hopelessly incurable lesions must depend upon the surgeon's judgment as to the degree of physical and mental satisfaction which will be gained by such an operation for each patient.

Gastrostomy in patients with non neoplastic curable lesions of the hypopharynx, esophagus and esophagogastric junction serves admirably as a means of furthering the local treatment of these areas. When the nutritional need is great in these patients, the nutritional response is maximal only when the gastrostomy feeding is supplemented by an oral diet.

A satisfactory state of nutrition is best maintained in esophagectomized patients when they are able to ingest a diversified diet through either an artificial or a surgically reconstructed esophagus.

HARRY W. FRICK, M.D.

Hypertrophic Pyloric Stenosis in the Adult (Stenosis pylorica hypertrofica dell'adulto) RAFFAELE MAZZETTI.
Gior. ital. chir. 1948, 4, 65.

The case reported by Mazzetti occurred in a woman 44 years of age who had been in good health until the age of 25 when the first gastrointestinal disturbances appeared on the occasion of her first pregnancy and persisted for about 3 months after delivery. She was then well for 2 years, after which the symptoms recurred. Three years later during her second pregnancy the symptoms became worse and persisted since then with the exception of rare and short intervals. The symptoms consisted of epigastric heaviness, moderate pain, slow and difficult digestion, frequent eructations and sometimes nausea and vomiting. Gradually the patient has lost considerable weight. For the last 3 months her symptoms had been worse and the resulting anorexia reduced her to complete inactivity. Sedative treatment afforded no relief.

On admission the abdomen was not painful on superficial palpation, the stomach was partially filled with fluid. Roentgen examination revealed a picture

of gastric ptosis with marked delay in emptying. Laparotomy disclosed a dilated stomach with a strongly hypertrophic pyloric ring and stenosis. There was moderate perigastritis and periduodenitis at the posterior aspect. A Hoffmeister Finsterer gastric resection was performed. The histologic diagnosis was hypertrophy of the pylorus.

It was difficult to establish with certainty what the real cause of the hypertrophy of the pylorus had been. It could not be attributed to an inflammatory process or to ulceration because the histologic examination excluded this possibility. The mild perigastritis and periduodenitis had to be considered secondary to the hypertrophy because these irritative conditions were too slight to have determined such a conspicuous hypertrophic change. Besides these conditions are encountered rather frequently and have a silent course, while pyloric hypertrophy is rare.

It seemed probable that the present case like other similar ones represented a congenital hypertrophy which had long remained latent and had been stimulated by the occurrence of a banal gastritis during pregnancy. That the gastric disturbances were the contributing factor was suggested by the fact that they were the only data worthy of consideration in the history of the case. In addition other authors have reported that mild gastritis is capable of making manifest a latent state of hypertrophy.

The correct diagnosis was made only at operation. Gastric resection was favored because the condition of the patient allowed it and only a radical operation affords protection against possible recurrence and malignant degeneration. When the patient was seen 10 months after operation she had gained considerable weight, had not had any more digestive disturbances, and was in good general condition.

RICHARD KEMEL, M.D.

Reduction of Intussusception by Hydrostatic Pressure: An Experimental Study. MARK M. RAVITCH and ROBERT M. McCUNE, JR. *Bull. Johns Hopkins Hosp.* 1948, 82, 550.

This work was undertaken in order to determine experimentally the likelihood of perforation when intussusception is reduced by hydrostatic pressure. The intussusception was produced in dogs by stimulating a portion of the terminal ileum with a faradic current from an induction coil, seizing it with rubber shod forceps while still contracted and inverting it into the distal segment. If the entire intussusception was produced in this manner the serosal surfaces were sufficiently traumatized so that firm adhesions developed within 12 hours which made reduction impossible by hydrostatic pressure and difficult by direct manipulation. Therefore in subsequent animals the intussusception was initiated in this way with forceps and continued the rest of the distance with a smooth glass rod. Intussusceptions of 15 cm. in length were regularly produced.

It was shown that except in one animal whenever an intussusception could be reduced by hydrostatic pressure the animal survived indefinitely.

The mortality of subtotal resections in which all gross disease is removed has been 3 per cent in the last 5 year period.

The number of patients not subjected to operation has declined. Seventy five per cent have an operation. Fifty per cent of the total have a gastrectomy either subtotal or total.

The best palliative operation if gross disease can not be removed is subtotal gastrectomy.

The 5 year survival rate is now 7 per cent of the entire group that enters the hospital.

The best method now available to increase the number of cures of cancer of the stomach is to reduce the delay from the onset of symptoms to the surgical intervention.

CHARLES BAKER, M.D.

The Problem of Gastric Cancer in a University Hospital. *ILLIANN BRILL. Surgery 1945, 2, 15*

This brief statistical study from the University of California Medical School presents figures in substantial agreement with those from similar institutions.

There were 540 patients with carcinoma of the stomach of whom 60.2 per cent were operated upon, and 34.4 per cent of the total were resectable. Therefore in 65.5 per cent or approximately two-thirds of the patients seen a curative type of surgery could not be attempted.

The lesion at the pyloric end of the stomach accounted for more than 60 per cent of the cases resected. Of the 157 patient with lesions at the pyloric end 14 (8.9 per cent) were alive longer than 5 years and 30 others were alive but had not yet reached the 5 year period. Other lesions of the stomach offered less hope since of the patient being alive after 5 years however of 40, 8 were alive but had not yet reached the 5 year period.

The operative mortality dropped from 22.2 to 1.9 per cent in the last 5 years.

The point stressed is that better training of all physicians and earlier diagnosis or examination for cancer of the stomach could increase the number of cases suitable for resection and that doctors and laymen should be acquainted with the cure rate in cancer of the stomach so that they will not blindly accept a fatalistic attitude when the diagnosis is made.

FREDERICK C. HODGKIN, M.D.

Total Gastrectomy with Esophagoduodenal Anastomosis. *JAMES T. PRATER and FRANK KERN. Arch Surg 1945, 50, 45.*

The purpose of this article was to draw attention to one method of restoration of gastrointestinal continuity after complete removal of the stomach, which has received little consideration in recent years.

Interest in this subject, on the part of the authors, is stimulated by 2 recent cases in which the pathologic process and anatomic relationships were such that the duodenum could be readily anastomosed to the esophagus after removal of the entire stomach.

Previous experience with esophagoduodenal anastomosis after total gastrectomy was mentioned briefly.

The 2 cases in which this type of operation was

performed recently are presented. It was concluded that this procedure is suitable only in a selected group of patients. The technique of operation is briefly described. Esophagoduodenostomy is considered advantageous when practical because of its comparative simplicity and the elimination of unnecessary suture lines, and also because of the more nearly normal anatomic and physiologic restoration of gastrointestinal continuity which results.

Gastrostomy. DONALD R. COOPER and ROBERT W. BUCKTON. *Surgery 1945, 13, 311.*

Gastrostomy, as a measure for the control or improvement of the nutrition of ill patients, has long been a standard surgical procedure carried out upon selected patients. In a recent editorial, however, it was indicated that the life expectancy of the majority of patients upon whom this procedure is carried out is little or possibly adversely affected by this operation.

The performance of gastrostomy is one of the earliest of surgical procedures. Because of some of the technical difficulties encountered in carrying out this simple operation or because of the subsequent unsatisfactory functioning of the gastrostomy many methods and variations have been advocated by various surgeons. At the present time the fashioning of a gastrostomy is varied by each surgeon to meet the needs of a particular situation and little importance is attached to the use of difficult or elaborate techniques. Since many gastrostomies are considered temporary expedients and not permanent fistulas, the simpler procedures are believed to be most suitable. In many instances, because of the poor general condition of the patients, the simplest procedure carried out under local anesthesia is obligatory.

In attempting to correlate the surgical complications and the difficulties entailed in the postoperative feeding regimes a detailed examination of each complication in relation to the surgical technique used was made. The percentage of complication encountered in each instance was, with one exception, without significant difference. A significantly greater number of patients experienced stomal malfunction after the Stamm type of gastrostomy.

Again the type of anesthetic agent was implicated in the production of increased morbidity and mortality rates. In each case the anesthetic agent in a series of patients was chosen to meet the qualifications of the patient and the requirements of the surgeon. In a group of 194 patients, gastrostomy was carried out 109 times with local procaine infiltration anesthesia, 79 times under general inhalation anesthesia, and 6 times with spinal anesthesia. No clear-cut correlation between postoperative complications or death and the incorrect choice of anesthetic was noted.

In 82 patients (42 per cent) of the 194 upon whom gastrostomy was performed no postoperative complications occurred. In the remaining 112 patients a total of 147 complications occurred.

Modern Trends in Surgery of the Colon MORRIS BEREND and ALBERT BEREND *Surg. Clin. N. America* 1948 28 515

The authors have discarded the Mikulicz operation except in those patients with absolute intestinal obstruction. Its undesirable features are that it is a staged operation and that it requires long hospitalization with its attending economic strain on the patient. Notwithstanding the fact that it is one of the safest operations to perform on the colon, the disadvantages as cited are so great that it has been replaced by other simpler and less time-consuming procedures.

The newer procedures have been made possible by better knowledge of the physiology anatomy and the application of chemotherapy before and after operation. This knowledge is applied in the form of preoperative and postoperative precautions which must be adhered to so that the best results may be obtained. The operation, dependent upon the anatomicopathological location of the tumor is described. The one-stage resection and primary anastomosis of the colon when the lesion is proximal to the rectosigmoid junction is strongly recommended. Even here when the colon and lesion can be mobilized it may be possible to perform this operation. Beyond the rectosigmoid junction the Miles operation is employed. The Babcock Bacon operation having proved less satisfactory in the author's hands.

Old age is not considered a deterrent to operation for cancer of the colon. The case of an 85 year old patient is discussed as also is a case of melanosis of the colon exhibiting the same symptoms as were found in carcinoma of the colon.

STEPHEN A. ZIEGLER M.D.

Factors Influencing the Healing of Anorectal Surgical Wounds. JOHN MCGIVREY *South. M. J.* 1948, 41 401

The factors which influence the healing of anorectal wounds are the general condition of the patient, rest of the part, the presence of foreign bodies in the wound, the blood supply, incomplete removal of the lesion, infection and the behavior of the wound.

There are two principal forces acting upon wounds in this area—one in a medial and cephalad direction and one in a side-to-side fashion. If a surgical wound in this region is of such a character that the medial and cephalad forces acting upon it predominate, there will be a great tendency for the outer extremity of the wound to be drawn into the anal canal, with the likelihood of its becoming undermined with resultant postoperative sinus and abscess formation. This is particularly true when the wound is located in the anterior or posterior commissures of the anus where the fibroelastic extensions are much more numerous. If a sinus or an abscess develops in the wound the prolonged infection leads to the formation of an excess of scar tissue and a delay in the covering of the wound with epithelium. In order to avoid this complication surgical wounds of this area should always be extended outward beyond the in-

fluence of the fibroelastic extensions so that the medial and upward force has little or no influence upon the wound and it is permitted to heal side-to-side. The wound edges should be beveled and the longitudinal ends tapered so that there is a gradual slope to the skin surface in all directions. This type of wound is not likely to become complicated by 'bridging' or undermining of its edges. The problem of wound healing resolves itself into one of making every effort to minimize infection and of promoting local resistance of the tissues.

Sulfathiazidine given by mouth has been found to be effective in diminishing the infection of anorectal wounds.

The postoperative care of an anorectal wound largely determines the rate of its healing. Oxycel gauze as a postoperative dressing will greatly decrease postoperative bleeding and will not interfere with healing of the wound. The gauze is liquefied and absorbed or discharged from the wound in 72 hours. The wound is examined daily, spreading apart the buttocks and separating the edges of the wound. This tends to discourage early 'bridging' of the tissues. Eumucin is applied to the wound with a small sterile cotton tipped applicator at each examination. On the second postoperative day warm moist applications are applied to the wound and on the following day after an enema brings the first bowel movement, hot sitz baths are given the patient. While in the tub the patient is instructed to hold his buttocks apart so that the water may enter the anal canal. Sitz baths are repeated twice daily. In the interval a soft piece of cotton is placed in the wound to protect its surfaces from physical injury.

After the patient leaves the hospital he is seen twice weekly in the office and at each visit the wound is inspected for bridging, pocketing, or undermining of its edges. The appearance of an excess of granulation tissue usually indicates bridging of the wound, sinus formation or undermining of the wound edges. When these complications of healing are discovered they should be corrected immediately. Granulation tissue tabs should be excised and the flat granulating surfaces which project above the skin surface should be treated with a silver nitrate applicator. Undermining of the wound edge is usually present in the longitudinal end of the wound and is treated by raising a small wheal of procaine in the skin over the area and opening up that portion of the wound with a small pair of scissors. The edges of the skin are then trimmed back and bleeding is controlled with an oxycel dressing.

CHARLES BARON M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

The Use of the Long T Tube in Surgery of the Biliary Tract. RICHARD B. CASTELL *Surg. Clin. N. America* 1948 28 659.

The author discusses the uses of the long T-tube in surgery of the biliary tract. In contrast with the

Pathological studies indicated that the returning limb was regularly found to be severely damaged, even at the point of gangrene at a time when the bowel in the entering limb was still viable. This was undoubtedly due to the devascularization of the returning limb by the acute kinking of the bowel as it turned on itself at the apex of the intussusception. Hemorrhage and engorgement disappeared first after reduction, then edema, and lastly cellular infiltration. The mucosa is frequently partially sloughed or eroded and pathogenic bacteria made their way through the serosal surface even in bowel which appeared apparently preserved. This may have been a partial explanation of the fever seen clinically after reduction and of the frequency of abscesses and infection after operative reduction.

Intussusception was observed at 19, 35 and 38 hours of duration. It may be reduced by a hydrostatic pressure of 15 feet. Intussusception of 48 hours of duration may still be reducible by hydrostatic pressure.

HAROLD LATHAM, M.D.

Mucocoeles of the Appendix with Tumorous Tendencies (Les mucocœles de l'appendice à déterminations tumorales). M. CH. ROUX and L. M. ROUX. *J. Ch. Par.* 913, 64, 5.

Mucocoele of the appendix may produce a rare type of palpable tumor in the right side of the abdomen or flank. The authors report such a case in a 35-year-old woman. The history and findings are reviewed.

A right pararectal incision is recommended for exposure of these lesions because it permits exploration of the region and excision of a free mucocoele and because it can be extended proximally to permit hemicolectomy when necessary.

LOW ROUX, M.D.

Surgery of the Lower Bowel. H. ST. E. BAGO and ROBERT J. RWE. *J. Am. M. A.* 913, 30, 975.

The authors report a reduction in the mortality rate for colon resection from 6.4 per cent in 346 cases observed prior to January 1936 to zero of 143 cases observed subsequent to that date. This low figure is attributed to careful preoperative evaluation, preparation and postoperative care. Surgical technique is not discussed.

The patient who requires colon surgery should be hospitalized for several days prior to the operative procedure. During this time he is carefully evaluated as to surgical risk. Every means is utilized to place him in optimal nutritional, fluid, electrolyte, nitrogen and vitamin balance. His pulse and renal function must be corrected. The bowel is prepared with a combination of phthalylsulfathiazole and streptomycin; the latter being limited to the period from 48 to 72 hours immediately before surgery to avoid the development of streptomycin resistance.

Proper postoperative management embraces adequate nutrition and fluid balance. Penicillin is given routinely. Anal spasm is relieved by anal motor analgesic therapy. The best prophylaxis for throm-

boembolism. Other postoperative complications and means to prevent them are described.

EDWARD W. GIBBS, M.D.

Clinical Aspects of Carcinoma of the Cecum and Ascending Colon: Report of 68 Cases. CHALLICE H. BROWN, JAMES R. COLVERT, and BROCK E. BRUSH. *Ann. Int. M.* 1943, 38, 940.

The authors analyze 68 case histories of carcinoma of the cecum and ascending colon. The predominant symptoms were pain (76 per cent), obstruction with cramps and colic (38 per cent), vomiting (31 per cent), diarrhea (30 per cent) and anemia with less than 13 gm. of hemoglobin (79 per cent) and with less than 11 gm. (54 per cent).

The most noteworthy findings were that 32 per cent of the patients had an annular type of growth and 35 per cent a constricting or obstructive lesion. The immediate postoperative mortality in the last 5 years was 8 per cent. Seventy-one per cent of the patient with no evidence of metastases are living for an average of 3.8 years after operation, whereas 29 per cent with metastatic lesions are living on an average of 4 years after operation.

STEPHEN A. ZINN, M.D.

Microcolon. JONAS ZINZEL. *Acta radiol. Stockh.* 913, 29, 12.

The congenitally small colon or microcolon designates a condition in which the entire large bowel (except the rectum) of a newborn infant is anatomically found to have a diameter of around 4 to 8 mm. The condition has been reported rather infrequently. There are two types of microcolon: the primary and the secondary. In both types microscopy reveals a perfectly built normal bowel, consisting of all layers but with a small lumen. The primary type according to various authors is attributable to developmental factors: primary dilatation and hypertrophy of the small intestine, primary hypoplasia of the colon, temporary incarceration of a segment of the small intestine changes in the innervation, and mechanical factors while the secondary type is due to organic obstruction. The author presents the findings in 3 cases, one of each type.

The following two roentgenologic features are stressed: (1) the absence of fluid levels in the intestinal tract on vertical roentgenograms must be due to the liquid content in the bowel and is probably pathognomonic of meconium ileus, and (2) the absence of haustra or plicae circulares in the small intestine, which makes it almost impossible to distinguish between the small bowel and the colon.

In cases of organic obstruction two points should be noted: fluid levels are often present and hard, granulated fecal matter is not seen in the roentgenograms.

Barium enema may be of diagnostic value. A barium meal is usually contraindicated. The roentgen examination is usually of value in establishing the diagnosis of microcolon.

FAYE L. HENRY, M.D.

before the development of marked inflammatory changes and before the development of serious complicating factors which so profoundly influence morbidity and mortality.

A careful study of this series of 74 pathologically proved cases of acute cholecystitis and of their clinical manifestations confirms this conclusion of the unpredictability of clinical signs and laboratory findings in estimating the degree of inflammatory change.

Furthermore the inability to follow the pathologic process accurately by clinical means is illustrated by the fact that perforation occurs in from 6.82 per cent (Bachhuber) to 13 per cent (Clagett) and to 20 per cent in the large collected series reported by Heuer. The average reported mortality in cases of perforation is about 45 per cent. This does not include other or subsequent sequelae of a perforated viscus. There were 9 perforations among the 74 cases reported.

The highest mortality still remains in the older age group who have concomitant organic disease. In Bachhuber's series, 69.23 per cent of the patients were over 63 years of age and almost all had had repeated attacks as well as concurrent disease. M. K. Smith stated that the fatalities are confined to the older age group and that peritonitis is not so frequently a cause as suspected. Eliason and Stevens found the mortality after 60 years to be eight to ten times greater than that before the age of 60, they also discount the factor of infection as a contraindication to early operation. Bachhuber best summarized the situation when he wrote "For the more recurrent attacks the patient has the older the age, the more likely it is that the patient may also be suffering from some serious concomitant disease all of which contribute to the mortality."

Stones in the common duct are more often an accompanying feature of acute cholecystitis than is generally thought. Thirty five of the 74 patients whose cases are reported had common duct explorations. Stones were found in 12 cases an incidence of 16.2 per cent which very closely parallels the occurrence of common duct stones in the chronic calculous gall bladder. Common duct stones should be searched for just as carefully in acute disease of the gall bladder as in the chronic noninflamed gall bladder and will just as frequently be found.

Cholecystectomy was accomplished in 73 cases. In 51 cases however the operating surgeons elected to do the dissection from the fundus to the cystic duct instead of carrying out a retrograde dissection as is the usual method in this clinic. The marked edema makes this method of dissection easier and safer in most cases since it permits easier visualization of the cystic artery, cystic duct, and also the common duct which may be obscured by the marked edema which often involves the tissues over the common duct to a marked degree. Of the 11 patients operated on within 48 hours of the onset of symptoms 5 had dissections from the fundus to the cystic duct and 6 in the retrograde manner. Perhaps the sulfonamides and antibiotic agents will in many instances affect the time of surgical intervention but undoubt-

edly if the acute gall bladder were considered and treated as any other acute abdominal emergency morbidity and operative risk could be kept at a minimum. These therapeutic agents are by no means a substitute for urgent surgery.

The authors have reported a consecutive series of 74 pathologically proved cases of acute disease of the gall bladder with 1 postoperative death, a mortality of 1.3 per cent.

Acute cholecystitis is an acute surgical condition in which early operation preferably within 48 hours after the onset of symptoms permits a more thorough operation at less expenditure of time, money and suffering on the part of the patient as well as reduction in the operative risk. Because of the relatively high incidence of common duct stones they should be carefully sought for and removed in acute disease of the gall bladder as in other cases of disease of the gall bladder. Cholecystostomy has a limited indication in the treatment of acute cholecystitis but is a valuable surgical procedure in some cases. Early operation should reduce the mortality in the older age group as it lessens the hazards of depleted reserves in cases of concomitant disease. In an editorial entitled "Acute Cholecystitis—Why Delay?" C. G. Heyd wrote "The indication is to operate carefully with due celerity, relieve the mechanical obstruction and provide drainage. Teachers of surgery who lend their prestige and give support to a policy of waiting provide authority for timid surgeons in experienced operators and procrastinating practitioners."

BENJAMIN GOLDMAN, M.D.

The Surgical Treatment of Acute Cholecystitis. FRANK GLENN, Surgery 1948 23 397

The philosophy of surgical removal of the gall bladder early in the acute phase of cholecystitis is based on the premise that removal of the gall bladder interrupts the pathologic process and averts the danger of gangrene and perforation. The procedure is contraindicated in the presence of peritonitis due to perforation of the gall bladder, when there are technical difficulties which make it impossible to identify important structures. In the presence of severe obstructive jaundice, and in patients whose general condition is so grave that they will not tolerate such an extensive procedure.

The patients over 50 years of age offer a much greater risk both because of more advanced disease of the biliary system and because of the frequency of a serious concomitant disease.

There were 586 patients in the series treated by early surgery. The over-all mortality was 17 deaths or 2.8 per cent. There were 381 patients under 50 years of age with a mortality of 1.04 per cent while in the group over 50 years, comprising 205 cases the mortality was 6.1 per cent. The mortality following cholecystostomy and common duct exploration was relatively higher which indicated that there was a much greater initial risk in the latter group.

The author believes that early operation for acute cholecystitis, both in relation to the individual at

common T tube which has a 2 1/2 inch transverse limb. The long T tube has a 12 inch horizontal limb which the approximate length of the vertical portion. It may be either of the usual red rubber or of pure or of synthetic rubber. Because of a problem in using it is easier to join the equal length of tubing to the midportion of one so that each end is 6 inches long.

I reviewed the records of patients who have been encountered by the patients after obstruction of the biliary duct persisting after previous operation. The author believes that such unsatisfactory results may be avoided by employing the long T tube with the distal limb passing through the papilla into the duodenum. This tube is specifically indicated for: (1) the common duct stones; (2) fibrosis of the papilla; (3) repair of benign strictures; (4) malunion of the bile duct; (5) certain gastroduodenal resections; in duodenal ulcers; and (6) duodenal diverticula.

The author discusses the theoretic objections to placing a tube through the ampulla, particularly the possibility of reflux of the duodenal content into the biliary duct system. In his large experience he has never observed the occurrence of this complication. These patients have a rarely developed attack of cholangitis as evidenced by the occurrence of transient jaundice, rigors, chills, a fever, even though the tube is left in place for a year or more that use of the long T tube is not contraindicated. The author fully, however, emphasizes that these tubes require irrigations throughout the time they remain in place. During the immediate postoperative period saline irrigation can be utilized and thus the amount of trauma to the papilla may be decreased.

ROSE T. WELLS, M.D.

Congenital Cystic Disease of the Liver. LAWRENCE C. WELLS. *Ill. J. Surg.* 91: 56, 93.

Neoplasms of the hepatic cysts occur singly in small or large groups or in extreme profusion. The author reports 3 cases illustrating the various features of congenital cystic disease. Clinical differentiation between the solitary cyst and polycystic disease remains impossible. In these two conditions the treatment is the same, the prognosis differs. In the solitary cysts there are often pedunculated nodules, while in polycystic disease the nodules are large or minute. In the parenchyma together with the biliary structures or occurs in association with cystic degeneration of the kidney or some other organ. The use of a pyloric variable occlusion to cover the removal of polycystic malformation has been accomplished successfully, but has a special disadvantage in that it inhibits the drainage of all the general biliary surgical procedure in all polycystic disease of the liver.

In the treatment of polycystic disease the use of a pyloric variable occlusion offers the only real hope of cure. The radical procedure may be the only method of curing the disease and in the

kidneys or another organ. Ordinarily the anatomic situation can be defined only by exploration, at which time a choice must be made between excising the involved portion of the liver or doing nothing. Excision of the lesion is contraindicated in the presence of ascites or in cystic disease of the liver without symptoms.

The earliest symptoms often proceed from the associated polycystic disease of the kidneys. Polycystic disease of the liver may not interfere with good health since symptoms are usually due to pressure. Liver function tests are ordinarily normal. The right lobe of the liver is involved about 5 times more often than the left and women are more frequently affected than men. Approximately one half of the reported cases of congenital cystic disease of the liver have been polycystic and the average age of the patients has been 33 years. No pathognomonic features are produced by the cystic liver.

JOHN L. LINDQUIST, M.D.

The Acute Gall Bladder. SAMUEL F. MARSHALL and E. S. PHILLIPS. *Surg. Clin. N. America*, 1913 58, 633.

Acute conditions of the gall bladder should very properly be classified as emergencies, and surgical treatment should be undertaken as early as the general condition of the patient will permit.

The authors report a series of 74 patients with acute disease of the gall bladder who submitted to operation. The diagnosis had been established by careful pathologic examination of the removed specimen.

In 1923 Walton of England proposed operation early after the onset of the disease process and there by precipitated a more or less controversial discussion of surgical management. It relates to the optimal time for surgical intervention. In 1930, in this country many surgeons questioned the advisability of this method of surgical treatment and by 1933 many articles appeared in the literature with propositions for both the immediate and delayed methods of surgical treatment.

Statistics are cited to support both viewpoints but are very often the definitions "early" and "immediate" operations had diverse meanings in the different series and consequently permitted no comparison of surgical result. The authors believe that a more logical approach to the problem would be to define early operation so to include those patients operated on within 72 hours of the onset of acute symptoms. "Immediate" after from 2 hours to the complete cessation of clinical manifestations and "late" as 3 or more days after the clinical remission of objective individual symptoms. They would prefer to regard all cases of this nature as emergencies to admit all patients at once to the hospital and to operate soon the diagnosis can be established, the patient's general condition can be evaluated, and the chemical fluid balance can be restored. These operations should very properly be listed as "early" surgical procedures. This should be the ideal method of the time at which operation could be carried out.

the development of marked inflammatory process and before the development of serious complicating factors which so profoundly influence mortality and mortality.

A careful study of this series of 74 pathologically proved cases of acute cholecystitis and of their clinical manifestations confirms this conclusion of the unpredictability of clinical signs and laboratory findings in estimating the degree of inflammatory change.

Furthermore the inability to follow the pathologic process accurately by clinical means is illustrated by the fact that perforation occurs in from 6.82 per cent (Bachhuber) to 13 per cent (Clagett) and to 20 per cent in the large collected series reported by Heuer. The small intracystic gall bladder is not considered an indication for cholecystectomy. The incidence of retained calculi in this study was 6 per cent. The length of time a tube remained in the ducts depended on the findings during the operation. Calculi were found in 100 instances.

Table I shows the complications following cholecystectomy in 439 cases. Table II shows the indications for cholecystectomy in 61 cases with nonpalpable calculi. RICHARD J. LEVY, JR., M.D.

Some Experiences with Anastomosis of the Common Bile Duct to the Duodenum and Repair of Strictures of the Common Bile Duct

The anastomosis of the common bile duct to the duodenum is a procedure which has been described by many authors. The purpose of this paper is to report the results of the author's experience with this procedure. The author has performed this procedure in 100 cases. In 75 cases the anastomosis was performed with the common bile duct and the duodenum. In 25 cases the anastomosis was performed with the common bile duct and the jejunum. The results of the procedure are as follows:

Two of the patients succumbed to cancer within a year of surgery and the remaining 5 were well from 2½ to 6 years after operation. Three patients of the 10 died reasonably well over a period of from 2½ to 3½ years after operation but had attacks of chills fever and jaundice.

In 3 cases of the original 13 a satisfactory result was obtained with end-to-end suture of the duct for 3½ to 8 years respectively after operation.

Based upon his experience with these cases the author makes several observations pertinent to the surgery involved. He believes that a Roux-Y procedure with a defunctionated loop of jejunum anastomosed to the common duct is the procedure of choice when simple end-to-end anastomosis of the duct cannot be accomplished. However his success with this group of cases supports his statement that simple choledochoduodenostomy is a valuable procedure in patients unable to stand the more extensive surgery necessary in a Roux-Y procedure.

Several points in technique and management are emphasized. First the obvious necessity of returning these patients to physiologic and nutritional balance before surgery is attempted is stressed. Vitamin K in large doses is a necessity.

Locating the proximal end of the common duct is enhanced by sharp dissection close to the under surface of the right lobe of the liver and approaching the hilum from the anterior and to the right. The bulbous end of the common duct appears as a bluish tinged cystlike structure shining through the scar tissue. The distal end can almost always be found by mobilizing the duodenum and reflecting it to the left to pick up the retroduodenal position of the duct.

Vitallium tubes are difficult to keep in place for long periods of time and tend to plug with biliary concretions and therefore they are probably inferior to either a fenestrated catheter or a T tube which can be securely held in place and removed when desirable.

Mucosa-to-mucosa anastomosis is more desirable even if there is slight biliary leakage, than is serosa-to-serosa anastomosis. The latter is liable to lead to stricture if epithelium partly lines the anastomosis. FREDERICK C. HOBBS, M.D.

Surgical Treatment of Carcinoma of the Ampulla of Vater and the Extrahepatic Bile Ducts. A Review of 51 Cases and Max M. Zinswiler, Arch Surg 1948 5: 199

Treatment of cancer of the ampulla of vater and of the extrahepatic bile ducts is often delayed in the attempt to make a correct clinical diagnosis. Since the problem of diagnosis and treatment may be considered the same for the two conditions, accurate clinical diagnosis is not as important as early diagnosis of a suspected cancer in this region followed by prompt exploration. Only when this principle is followed will the resectability and cure rate improve. The experience with these cancers during the 10 year period from 1937 to 1946 during which time 51 patients were admitted to the surgical service

of the Cincinnati General Hospital, is reported. Both cancers are rare.

Carcinoma of the ampulla of Vater constitutes about 1.15 per cent of all cancers in autopsy statistics. Eight cases were observed at the Cincinnati General Hospital during the 10-year period: a clinical incidence of 0.27 per cent. The average age was 57.3 years. Six occurred in males, a sex incidence of 3 males to 1 female. The average life expectancy in untreated cases after the onset of symptoms is from 3 to 8 months, with death resulting from liver damage.

The important findings which lead to a working clinical diagnosis of carcinoma are: (1) persistent epigastric discomfort; (2) pain; (3) anorexia and weight loss; (4) obstructive jaundice; (5) anemia of secondary type; (6) persistent occult blood in stool; (7) blood in duodenal secretion; and (8) roentgenologic evidence of a filling defect or "reversed 3 sign" in the peripapillary region.

Pain, although a characteristic symptom, is of no definite type. The persistence of occult blood in the stool is regarded of major importance. The differential diagnosis can be established only by exploration.

The treatment of choice is partial duodenopancreatectomy. Whether operation is a one-stage or two-stage procedure must be left to the judgment of the surgeon in the individual case. Among the 8 cases the resectability was 50 per cent. One patient is living after 5 years and 10 months; another lived 7 years and then died of metastatic melanoma of the skin.

Ten cases of carcinoma of the extrahepatic bile ducts were seen in the 10-year period, a clinical incidence of 3.6 per cent. Autopsy statistics indicate the incidence of these lesions to be about 0.13 per cent of all carcinomas. The average age of the patients seen was 61.3 years, with a sex ratio of 3 males to 3 females.

The differential diagnosis is the same as for ampullary lesions. Pain radiating through the back is helpful in early diagnosis. Partial choledochoduodenopancreatectomy is the most desirable operative procedure when possible.

Eight of the 10 patients were explored. Six were inoperable. In 1 patient palliative operation (first-stage Whipple) was possible, and in another radical resection was done. The latter lived 1 year and 5 months; none of the others lived longer than 3 months after exploration.

Ampullary carcinoma has a higher resectability rate than does carcinoma arising from the extrahepatic bile ducts.

FRANK B. QUEEN, M.D.

Phlebotromboses Associated with Mucin Producing Carcinomas of the Tail and Body of the Pancreas: A Clinicopathologic Study of 2 Cases with Necropsy. W. K. JENKINSON and WILLIAM O. RUSSELL. *Arch. Surg.* 94:5 361-66.

Contrary to cancers in other sites, pain is one of the earliest and most reliable symptoms of cancer of the body and tail of the pancreas, and upper abdominal

pain constitutes the most frequent complaint in this condition. Three types of pain have been described as typical of this disease: (1) dull, aching pain often referred to the back; (2) paroxysmal pain at the umbilical level, often referred to the back; and (3) right upper quadrant pain resembling that in biliary colic.

Venous thromboses are also reported as being frequently associated with cancer of the body and tail of the pancreas (up to 50 per cent in autopsy series). In several instances the symptoms of peripheral venous thrombosis constitute the patient's initial complaint. It may be that unaccountable phlebotromboses will prove an early clue to the existence of pancreatic carcinoma.

Two cases of mucinous carcinoma of the tail and body of the pancreas with multiple venous thromboses involving both the portal and systemic systems are reported in support of the observations reported. In one, pain was the first symptom. In the other it was unexplained phlebotrombosis of the leg. Since no adequate explanation for the multiple thromboses was revealed by autopsy in either case, some yet unidentified property of mucinous carcinoma of the pancreas is postulated as possibly being associated with thrombosis in these patients.

FRANK B. QUEEN, M.D.

A Technique for Pancreaticoduodenal Resection. RICHARD B. CASTELL. *Surg. Clin. N. America*, 1948, 43: 76.

The author considers four findings a contraindication to pancreaticoduodenal resection: (1) distant metastases; (2) local spread with direct invasion beyond a possible limit of resection; (3) involvement of the superior mesenteric vessels; and (4) involvement of the portal vein. The involvement of the superior mesenteric vessels can be determined by division of the gastroduodenal artery and incision of the peritoneum on the inferior border of the pancreas. Similarly the portal vein can be identified by division of the gastroduodenal artery and displacement of the common duct downward, which permits digital examination of the posterior surface of the head of the pancreas by displacing the portal vein backward.

The author prefers a two-stage procedure. At the first stage an antitoxic cholecystojejunostomy is done. If the lesion cannot be resected an enterocenterostomy is also performed. Also in nonresectable cases a side-to-side anastomosis is made between the pancreatic duct and the jejunal loop over a T tube when possible.

The second stage of the procedure is carried out by reopening the first incision and lengthening it. The previous anastomosis is freed up and displaced to the right and downward. The peritoneum over the kidney is incised to the right of the duodenum, and the duodenum and head of the pancreas are elevated and rotated to the left. This will expose on the posterior aspect of the abdomen, in turn, the spermatic or ovarian vein, the inferior vena cava, and the aorta.

SURGERY OF THE ABDOMEN

The lesser omental sac is entered through the anterior two layers of the gastrosplenic omentum at the extreme right margin. The posterior portion of the gastrosplenic omentum is then displaced downward which permits identification of the middle colic vessels. The peritoneum is incised to the right, the hepatic flexure and right half of the transverse colon are freed and displaced downward. The peritoneum is then incised at the inferior border of the pancreatic body to expose the superior mesenteric vein. The superior mesenteric artery is next identified and the inferior pancreaticoduodenal artery is ligated and divided.

The lower half of the gastrosplenic omentum is incised, the right gastric artery ligated and divided and the course of the hepatic artery determined. The gastroduodenal artery is identified where it leaves the hepatic artery. It will be found to have a very short trunk before it divides usually into four branches. This allows about 1 centimeter of the artery to be dissected free and divided between ligatures.

The common duct is then freed up and the site of entry of the cystic duct exposed. The common duct is displaced downward and the anterior surface of the portal vein visualized. A finger can be passed under the head of the pancreas on top of the portal vein, which has no branches and the finger is passed through so as to emerge below the body of the pancreas and anterior to the superior mesenteric vein. Careful palpation of the entire region can at this time determine the operability of the lesion before division of either the stomach or common bile duct.

The common duct can now be divided between clamps at the proper point. This will vary greatly according to the site of the malignancy. If the first stage operation has been done and the cystic duct found too close to the desired point of resection the common duct is severed and left for implantation in the jejunum beside the cholecystojejunostomy. In rare instances it will be found necessary to remove the gall bladder and disconnect the cholecystojejunostomy. In the two-stage procedure when the cystic duct is not near the point of division the common duct is carefully turned in by inversion sutures with silk for the outer layer.

The pyloric end of the stomach is then freed of its vessels and clamps are placed across it usually from $1\frac{1}{2}$ to 2 inches (3 to 5 cm) proximal to the pylorus. The proximal clamp on the stomach can be placed within the abdominal cavity on the left side of the abdomen which leaves the entire anterior surface of the body of the pancreas exposed.

The body of the pancreas is now lifted up on the finger and a point selected for transection. The main arterial blood supply of the pancreatic body runs along the superior and inferior aspects as longitudinal pancreatic arteries. Suture ligatures are placed on both superior and inferior aspects of the pancreas with nonabsorbable suture material to enclose about 1 centimeter of the pancreas. These are used in the distal portion of the pancreas near the line of resec-

tion. The pancreas is then transected bleeding from the proximal side being controlled with Allis clamps. The duct of Wirsung is dissected out before division. The duct is completed and left to project from the cut surface of the pancreas. This division exposes the portal vein and the junction of its tributaries the superior mesenteric and splenic veins. The pancreas is then closed with interrupted mattress sutures of silk the duct of Wirsung being left open. If the duct is dilated a catheter of appropriate size is placed in it if the duct is small it is ligated with fine plain catgut and then transfixed behind the tie by passing a braided silk suture halfway through it. The portion of the pancreas remaining is displaced to the left.

The transverse colon is raised and a point selected for division of the jejunum about 7.5 cm distal to the ligament of Treitz. The ligament of Treitz is completely severed and the proximal jejunum and fourth portion of the duodenum are freed. The mesentery of the proximal jejunum is then divided and the vessels are ligated. The jejunum is divided between clamps and the proximal end is closed, the sutures being left long for traction.

The division of the ligament of Treitz which frees the proximal jejunum beneath the superior mesenteric vessels makes a free communication between this area and the dissection previously carried out on the right side of the abdomen. The proximal jejunum and the fourth portion of the duodenum are drawn through beneath the superior mesenteric vessels to the right. By elevation of the duodenum and head of the pancreas, the uncinate process can be freed up posteriorly. This is the most difficult part of the operative procedure.

After elevation of the pyloric end of the stomach head of the pancreas, and duodenum the short branches of the superior mesenteric vein and superior mesenteric artery which go to the head of the pancreas the uncinate process and the fourth and third portions of the duodenum are then divided between clamps, which permits delivery of the specimen. Sheets of gelfoam or oxidized cellulose (oxycel) may be useful in the control of capillary ooze.

A point is then selected on the afferent loop of jejunum for the anastomosis of the pancreatic duct. If the duct is small, a pressure necrosing suture technique is used. Usually the duct of Wirsung will be large enough to permit careful suture over a rubber tube. The antimesenteric surface of the jejunum at the point selected is incised for the same distance as the width of the cut closed end of the pancreas. The jejunum is sutured to the pancreas with interrupted silk sutures passing through the area previously closed by the mattress sutures of the pancreas to prevent the sutures from pulling out. When the posterior suture line has been completed the mucosa of the jejunum is opened and two interrupted sutures of catgut are taken between the mucosa of the duct and the mucosa of the jejunum. A rubber tube is then inserted and anchored with a silk suture. Two interrupted sutures are taken in the mucosa anteriorly and the anastomosis is completed by interrupted

silk sutures through the anterior wall of the jejunum and pancreas.

In the two-stage procedure, the biliary tract anastomosis will have been completed by the first stage cholecystojejunostomy. In some cases it will be necessary to implant the common bile duct into the jejunum as an end-to-side procedure just proximal to the gall bladder. This is the same anastomosis as carried out in the one stage procedure and is done in two layers over a rubber tube.

If the enterocenterostomy was not done proximal to these anastomoses in the first-stage procedure it is done as the third anastomosis. The final procedure is an end-to-end anastomosis of the stomach to the jejunum.

A cigaret drain is placed down to the resected uncinate process and brought out between the biliary and pancreatic anastomoses through the upper portion of the wound. **EARL O. LATIMER, M.D.**

Total Pancreatectomy. JOHN M. WAUGH, *J. Am. M. A.* 1943 37 4.

Radical resection of the head of the pancreas and of the duodenum had been done 49 times at the May Clinic up to January 1, 1937. Eleven operations were for benign disease and 38 for malignant lesions. Six patients underwent total pancreatectomy with a death in the hospital.

The indications for resection of the head of the pancreas and total pancreatectomy for benign disease are discussed and it is emphasized that in such instances resection should be carried out only after careful evaluation of both the operative risk entailed and the disturbances in metabolism which might be expected.

Resection for carcinoma was accompanied by an operative mortality rate of 21 per cent. In the future this figure should become lower for already one-stage resection for carcinoma of the head of the pancreas has been performed 15 times with a hospital mortality rate of only 13 per cent.

A follow-up study of the 30 patients who had undergone resection for malignant processes prior to January 1, 1936 and had survived operation showed that 3 of 14 who had had carcinoma of the head of the pancreas and 5 of 8 who had had carcinoma of the ampulla of Vater were still alive on that date. The authors state that, other than surgical treatment there is no therapeutic measure available which gives these patients any chance for cure; hence, attempts should be constantly made to lower the operative mortality rate for the procedure and to improve diagnostic acumen so that resection can be carried out more often while the carcinoma is still in a curable stage.

Principal Indications for Splenectomy during Childhood. GEORGE VAN BUREN and GEORGE M. CURTIS, *Arch. Surg.* 1943 56 5.

The principal indications for splenectomy in childhood are thrombocytopenic purpura, congenital hemolytic icterus, and Banti's syndrome.

The presenting symptoms of 22 children with thrombocytopenic purpura were subcutaneous ecchymotic or petechial hemorrhages (91 per cent) bleeding from the mucous membrane (73 per cent) a history of bruising easily (32 per cent) and weakness (9 per cent). The results following splenectomy in this group of children have been outstanding.

Congenital hemolytic icterus is a chronic blood dyscrasia characterized by a microcytic anemia, increased red cell fragility, reticulocytosis, acholic jaundice, and splenomegaly. Occasionally "crises" occur. The presenting symptoms of 20 children with this disease were jaundice (70 per cent) weakness (40 per cent) pallor (35 per cent) splenomegaly (30 per cent) nausea and vomiting (10 per cent) chills and fever (0 per cent) and abdominal pain (5 per cent). In the critical state emergency splenectomy is the procedure of choice.

Splenectomy for Banti's syndrome is most successful if carried out in the early stages of the disease. **HOWARD W. GREEN, M.D.**

Spread of Carcinoma to the Spleen: Its Relation to Generalized Carcinomatous Spread. JOHN W. HARMAN and LEO DACONO, *Arch. Path. Chic.* 1943 45 9.

The authors studied the spread of carcinoma to the spleen and its relation to generalized carcinomatous spread. They studied only those cases of carcinoma in which there were secondary growths in one or more viscera within the thoracic and abdominal cavities regardless of the primary source. This eliminated the cases of carcinoma without metastases and those with regional spread only as well as cases of direct extension. Thus only 30 of 116 cases of carcinoma collected from a total of 663 autopsies performed in the years from 1915 to 1934 at the University of Wisconsin Medical School Hospital Madison met the projected requirements.

In addition to routine autopsy examination the spleen was paid to the spleen which was studied extensively grossly and microscopically. The criterion of Warren and Danks laid down in 1934, which regarded all noncontiguous masses of tumor cells as metastases was adhered to by Harman and Dacono. The pancreas was also examined specifically for secondary new growths because its arterial supply is associated with that of the spleen and because the pancreas is regarded as a rare site of metastases. Both organs derive their principal arterial supply from the same branch of the celiac axis, which would permit an equal chance of receiving hematogenous tumor emboli—a circumstance that might reveal any particular resistance of the spleen if there were a discrepancy in incidence. A special analysis of carcinomas of the stomach and the pancreas showed no peculiar propensity of these neoplasms to invade the spleen through the venous drainage system.

The authors found that in 30 cases of carcinoma in which metastases occurred in one or more organs in more than one body cavity the incidence of splenic and pancreatic metastases was 50 and 43

SURGERY OF THE ABDOMEN

per cent, respectively. In no instance were splenic metastases found apart from generalized spread in the gastric and pancreatic cases. The low occurrence of splenic metastases as compared with metastases in lymph nodes liver and lungs was due to inequality of exposure to metastases. When the exposure was equalized the spleen was not less susceptible than other viscera.

Ligation of the Splenic Artery in Patients with Portal Hypertension. TILDEX C. EVERTSON and WARREN H. COLZ. *Arch. Surg.* 1948 56 153

The operation of portacaval shunt for the relief of portal hypertension is a successful procedure for the good risk patient. However many patients are poor operative risks for such a formidable procedure. For the latter group the authors recommend ligation of the splenic artery.

Following ligation of the splenic artery in patients with portal hypertension there is an appreciable decrease in the size of the spleen but no evidence of necrosis. The veins transporting blood from the spleen are not disturbed and serve as channels for the escape of portal blood. The technique is simple. Three successful cases are reported in detail.

EDWARD W. GREEN, M.D.

Absorption of Blood from the Peritoneal Cavity. CLAUDE R. SKEAN. *Arch. Surg.* 1948 56 249.

Investigation shows that surgeons differ concerning the advisability of removal of fluid blood and clots from the peritoneal cavity after intraperitoneal hemorrhage or operative procedures. The purpose of the experiments was to determine the fate of blood introduced into the peritoneal cavity, its possible usefulness as a substitute for transfusion on occasions when the usual methods are inapplicable or too difficult, and its effect on the blood volume, hematocrit, reading hemoglobin and total protein levels. Addi-

tional observations were made to determine if the clinical leucocytosis so frequently observed after intraperitoneal hemorrhage is due to the hemorrhage alone or to the mere presence of blood within the peritoneal cavity. The response of the peritoneum itself to repeated intraperitoneal injections of autogenous blood was also determined.

A review of the literature concerning peritoneal absorption prior to 1923 was written by Cunningham. The method of administering blood by the intraperitoneal route as a means of transfusion or as a preventive measure against peritonitis or adhesions has been studied by many investigators. Some authors concluded that the presence of blood in the peritoneal cavity had no effect on the development of peritonitis while others reported that blood in the peritoneal cavity after abdominal operations offered protection against peritonitis and adhesions.

An increase in hemoglobin and in the erythrocyte count has been reported previously after the injection of blood into the peritoneal cavity but the response of the blood volume to hemoperitoneum has not been investigated.

Blood injected intraperitoneally is more rapidly absorbed if it is kept liquid by the use of an anticoagulant. Clotted blood is completely absorbed within 24 hours after injection. When uncitrated blood is injected clots from 0.5 to 8 cm. in size are observed at 4 days but are absorbed within 9 days after injection. Absorption of blood by way of the peritoneum will raise the blood volume to a maximum in 24 hours when 36 c.c. per kilogram of body weight are injected in dogs. The leucocytosis following hemorrhage into the peritoneal cavity is in some way due to the presence of blood in the peritoneal cavity itself and is not accounted for on the basis of leucocytosis caused by hemorrhage. Moderate peritoneal thickening, omental fibrosis and mesothelial proliferation without adhesions follow repeated intraperitoneal injections of citrated autogenous blood.

HARRY W. FINE, M.D.

GYNECOLOGY

UTERUS

Studies of the Uterine Mucosa. BERNIE FALCOWSKI. *Acta obs. gynaecol.*, 1943, 17: 139.

The author advocates that the various cyclic endometrial phases of the uterine mucosa be grouped as follows: (a) desquamation, (b) postmenstrual, (c) early proliferative, (d) late proliferative, (e) transition from the proliferative to the secretory phase, (f) secretion-preparedness, (g) midscretion, (h) late secretory and (i) premenstrual.

The menstrual or desquamation phase is characterized by (a) endometrial breakdown, hemorrhage and cell infiltration, (b) signs of secretory activity on the part of the epithelial glands, and (c) swollen cells of the stroma showing regressive changes. The diagnosis may not always be easy and the hemorrhages must be differentiated from those from other causes.

The postmenstrual phase overlaps the first week of hemorrhage; thus partly also overlapping desquamation. This is one of the stages in which the histological pictures present the greatest difficulty for diagnosis. This is true also in the transition stages between the proliferative and secretory phases, and at the stage of desquamation.

The early proliferative phase continues approximately to the tenth day of the cycle. Its transition from the postmenstrual phase is ill defined.

The late proliferative phase is characterized by a thick uterine mucosa containing corkscrew-shaped glands, the lumina of which are narrow and lined with an epithelium in which mitoses are scant and the edematous stroma is made up of stellate cells and coiled arterioles. It lasts to the fourteenth or sixteenth day of the cycle.

Transition from the proliferative to the secretory phase does not seem to last longer than 3 days. It probably occurs during the fourteenth to sixteenth days of the cycle. At this time ovulation takes place and the effect of luteinization becomes manifest. This is the time that Mittelschmerz, or intermenstrual pain, may occur with hemorrhage into the endometrium.

The early secretory phase or secretion preparedness is characterized by enlargement and tortuosity of the corkscrew-shaped glands, vacuolation of the epithelium predominantly in the basal zone, edematous stroma, and coiled arterioles. This phase continues to the eighteenth or nineteenth day of the cycle and is followed by the beginning of genuine differentiation.

Midscretion is a term introduced by American workers. It occurs approximately during the eighth to twenty-fourth days of the cycle. Genuine functional development of both glands and the stroma begins. Tortuosity of the glands becomes more marked, and there is definite evidence of secretory glands. The stroma begins to develop

In the late secretory phase the specific changes of the glands and stroma become more marked. The glands assume a saw tooth appearance. The stromal cells continue to accumulate nutrient substance and the arterioles become markedly coiled.

The premenstrual phase seems to begin only during the last 24 hours of the cycle. It is the transition stage to desquamation, a piecemeal affair which is characterized by crumbling and rapid necrosis of the endometrium and hemorrhage.

In analysing curettage material the pathologist should concentrate his efforts on establishing the endometrial phase as exactly as possible, not being content merely with diagnosis of the proliferative or secretory phase. On the other hand a diagnosis of, for instance, endometrium in the twenty-third day of the cycle is not reasonable in practice. This diagnosis is based on the assumption that the menstrual periods occur regularly every 28 days, which is rarely the case.

T. FLORELL, M.D.

Hystero-graphy as a Diagnostic Aid in Submucous Myoma. SYD ELLISON AND HENRY JENNISON. *Acta obs. gynaecol.*, 1943, 17: 367.

A brief history of hystero-graphy is given. It reveals the difficulty in the making of satisfactory hystero-graphs until the introduction of contrast media soluble in water which event increased the diagnostic value of hystero-graphy.

In describing the method, the authors emphasize the importance of avoiding contrast media which are too opaque otherwise minute structures may be concealed. The examination should be made under the fluoroscope. Several cases are reported and illustrated by figures.

The roentgenographic appearance of submucous myomas varies widely. However, they have one feature in common, i.e., a filling defect, which is regular in outline. Its shape varies with its size, the degree to which it projects into the uterine cavity and the extent to which it is attached to the uterine wall.

In the differential diagnosis, polyps of the endometrium are most important. The latter present an irregular shape and an uneven surface, they accommodate their growth to the shape of the uterine cavity and offer little difficulty in diagnosis. Firm polyps may be difficult or almost impossible to differentiate from myomas, particularly if the latter are pedunculated.

Hystero-graphy should be done in the first half of the menstrual cycle. However, if the contrast medium flows too rapidly through the uterus and takes into the abdominal cavity to permit the making of satisfactory roentgenograms, another x-ray study should be made at a later stage in the cycle.

In cancer of the uterus the hystero-graph reveals a uterine cavity with frayed and irregular contours and a defect in its filling.

GYNECOLOGY

The authors believe this method is a valuable diagnostic aid in submucous myoma and that it should be included in the routine examinations.

T. FLOYD BELL, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

A Contribution to the Study of Suppurating Dermoid Cysts of the Ovary with an External Fistula (Contributo allo studio delle cisti dermoidi ovariche suppurate e fistolizzate alla parete) GIOVANNI D'ERRICO *Gior Ital chir* 1948 4 99

Although cases of suppurating dermoid cysts of the ovary with an external fistula are exceptional, D'Errico has observed 2 at practically the same time. The first patient, a woman of 59, had had an acute abdominal syndrome 20 years previously characterized by pain in the left flank and moderate fever; she was operated upon after 8 days and a quantity of pus mixed with hairs was evacuated. It is most probable that the symptoms were due to an acute inflammation of the cyst rather than to a torsion of its pedicle. Fistula formation following the intervention represented the natural evolution of the process as suppuration continued because the cyst was not removed. Four years ago the patient was reoperated upon to free her from the fistula, but the intervention failed because nothing was done about the cyst. Finally, she came to D'Errico's clinic where the cyst and fistula were successfully removed.

The second patient, a woman of 52, had developed digestive disturbances 5 years ago and a diagnosis of cyst of the right ovary was made 3 years later. She had persistent fever which was attributed to suppuration of the cyst. She was operated upon but the surgeon did not succeed in removing the cyst because of adhesions and he limited himself to opening and draining it. The natural result was a fistula, through which some hair was eliminated about 5 months later. At D'Errico's clinic the cystic mass with scars and fistula was successfully excised. However, on the seventh postoperative day the patient developed an abscess in the right iliac fossa and fever which persisted after opening of the abscess and which resisted treatment for about a month, then disappeared suddenly on the occasion of anaphylactic shock caused by the intravenous injection of antiperitonitis serum.

An interesting occurrence in this case was the elimination of a living ascaris through the incision in the right iliac fossa without any sign of peritoneal irritation or formation of intestinal fistula. This could be explained by an adhesion of the bottom of the cystic abscess to one or more intestinal loops through which the ascaris could have made its way to the exterior without passing through the peritoneal cavity. The absence of intestinal fistula formation could be due to the small diameter of the worms (about 2 mm.) and to the thickness of the tissues separating the bottom of the abscess from the intestinal lumen and the varying consistency and structure which allowed spontaneous closure of the small break in the intestinal wall.

In both cases histologic examination of the removed mass confirmed the diagnosis of suppurating dermoid cyst established preoperatively on the basis of expulsion of hair through the fistulas.

RICHARD KEMEL, M.D.

Considerations on the Krukenberg Type of Ovarian Tumors (Considerazioni sulle tumori ovariche tipo Krukenberg) P. SARBU, V. VASILIU AND E. MIETES. *Gyn absz* Par., 1948 47 178

A woman of 36 was admitted with an abdominal size of a full term pregnancy. She complained of respiratory disturbances, loss of weight, difficulty in walking, and amenorrhea. Six months previously she had been operated upon for an inoperable tumor of the stomach with pyloric stenosis for which a gastroenterostomy had been performed. The amenorrhea had started a month before this operation and the abdomen had begun to increase in size shortly after the operation. Examination disclosed ascites and a hard, knobby, fixed tumor which reached under the costal margin and into the pelvis. Exploratory laparotomy revealed 2 tumors without adhesions; one involved the right ovary and was the size of a child's head, the other came from the left ovary and was the size of a large orange. Both were easily removed. Examination of the upper part of the abdomen showed the pyloric tumor surrounded by an epiploic mass. The abdomen was closed without drainage. Roentgen treatment was followed by slight amelioration of the general condition, but this did not persist because the gastric disturbances returned gradually. Histologically the tumors presented adenocarcinomatous formations of gastric type and Krukenberg's signet ring cells in a sarcomatoid stroma.

All authors now agree in considering this ovarian tumor as a metastatic localization of a tumor of the breast, the biliary tract, the colon, or the stomach especially of the last. Disagreement starts with discussion of the route by which the ovary is involved and the circulatory, retrograde lymphatic, and transperitoneal routes have all had their supporters.

The histologic characteristic of these tumors is the presence of signet ring cells and of pseudoglandular formations of digestive type in a sarcomatous mass. The particular aspect of these epithelial cells is due to compression by the surrounding sarcomatous tissue. The presence of mucus and the mucarmine reaction are not pathognomonic because mucous degeneration characterizes the evolution of most carcinomatous cells. The frequency of Krukenberg tumors among the solid tumors of the ovary is relatively high. From 20 to 25 per cent of the solid ovarian tumors are metastatic. The Krukenberg type of ovarian tumor is malignant despite the false impression of benignancy imparted by its mobility at operation. Malignancy of the tumor can be accepted in the presence of ascites, bilaterality, cachexia, and associated metastasis whether peritoneal, epiploic, or of other type.

Most authors recommend extirpation of the tumors followed by total hysterectomy and roentgen therapy, some oppose surgical intervention claiming that extirpation of the metastases stimulates the primary tumor; the present case seems to confirm this opinion.

Present knowledge of Krukenberg tumors suggests two practical considerations. Whenever hard bilateral ovarian tumors are found in the course of an operation, surgical and roentgen exploration of the digestive tract is indicated in search of the primary tumor. In view of the tendency of tumors of the digestive tract to metastasize, the question arises whether in gastrectomy for neoplasm it would not be advisable to extirpate the ovaries as a prophylactic measure, especially before the menopause.

RICHARD KEMEL, M.D.

MISCELLANEOUS

The Value of Celoscopy in Gynecologic Diagnosis
(Il valore della celoscopia nella diagnostica ginecologica). G. VACCARELLI. *Quel. d. n. stet. ginec.*, 947, 96.

Celoscopy or peritonoscopy introduced by Kelling in 1906 has been found by the author to be a valuable addition to the diagnostic armamentarium in gynecology.

The dangers of the method can be avoided by strict observance of the rules.

To explore the female reproductive organs, it is necessary to place the patient in Trendelenburg's position and the uterus in anteversion and elevation by means of an intrauterine probe.

The diagnosis by means of celoscopy was correct in 97.05 per cent of 70 cases in which the method was employed in the gynecologic clinic of Parma.

The method is of particular value for the diagnosis of ectopic pregnancy (follicular or corpus luteum cysts), inflammatory processes of the adnexa, genital malformations, and ovarian tumors.

If a small ovarian cyst or an accumulation of pus is encountered, an immediate injection of penicillin or sulfadiazine avoids complications.

The insufflation should be done slowly; the intra-abdominal pressure should be measured with a manometer and the injected gas should be sterile.

Of the different gases, oxygen is recommended because it is well absorbed and is nontoxic, but a danger is present when electrocautery is employed. The author uses Palmer Solari's celoscope. The use of the uterine probe is contraindicated in the presence of suspected or certain pregnancy, inflammatory or neoplastic changes of the endometrium, or imperforated hymen. The examination is performed under local anesthesia because a general anesthetic causes an abolition of reflexes so that the early signs of gas embolism, such as attacks of cough, may be suppressed. The celoscope may be introduced in the lower midline of the abdomen or through the posterolateral cul-de-sac, with the patient in the knee-chest position. The total amount of gas injected should

not exceed from 3,000 to 5,000 c.c., not more than from 500 to 700 c.c. being injected per minute. The pressure should not exceed 20 to 25 mm. mercury.

As to contraindications, excretion is advisable in the presence of cardiopathies, especially those involving the myocardium. According to some authors, the presence of acute inflammatory processes is considered a contraindication, but the writer found the method not only innocuous but extremely valuable in the differential diagnosis of appendicitis and acute salpingitis. The method should not be employed in the presence of a diaphragmatic hernia because communication may exist between the peritoneal and pleural cavities. Hemorrhagic diathesis also forms a contraindication. JOSEPH K. NARAY, M.D.

Surgical Experience in 51 Cases of Genitoabdominal Tuberculosis (Nuestra experiencia quirúrgica sobre 51 casos de tuberculosis genitoabdominal). C. FERNÁNDEZ RUIZ. *Rev. esp. Med.*, 1948, 5, 12.

It is the author's belief that tuberculosis of the female reproductive organs is much more frequent than is generally assumed. He reports 51 cases in which the diagnosis was verified at the operation and ascertained histologically.

The ages of the patients ranged from 19 to 59 years. Twenty-two of the patients were in the third, 22 in the first, and 7 in the fifth decade of life and 1 was older than 50 years. Forty patients were married and 11 were single. Of the 40 married women 31 were sterile. The following symptoms were present in descending order of frequency: dysmenorrhea, leucorrhoea, oligomenorrhea, and menorrhagia.

The correct diagnosis was made in 9 cases or 17.6 per cent. Hysterectomy and removal of the adnexa were done in 25 cases while various conservative procedures were employed in the remaining 26 cases. The postoperative mortality was 3.9 per cent. One patient who died had had an extensive suppurative peritonitis and the other had developed an exacerbation of his pulmonary symptoms.

In 8 cases suppurative peritonitis was present. In descending order of frequency, adhesive adnexitis, pyosalpinx, and obstructive nodular salpingitis were found. In 5 cases the uterus, tubes, and ligaments were involved.

A primary focus of infection in the lungs could be found only in 7 cases. In 2 Pott's disease was found, while in the remaining cases clinical and x-ray examinations failed to reveal the primary focus, which possibly was located in the abdominal lymph nodes.

Blood counts and determination of the sedimentation rate did not prove of any diagnostic value. The association of genital tuberculosis with other pathologic conditions of the same organs creates diagnostic difficulties. Fever in the past history should arouse suspicion. Amenorrhea in young persons should not be treated with hormones until a clinical and x-ray examination of the lungs has been done. Aggravation of dysmenorrhea by endocrine products justifies a suspicion of the tuberculous character of the condition.

GYNECOLOGY

The author's institute lacks an x ray apparatus and therefore his treatment is exclusively surgical. The type of operation varies according to the condition from unilateral salpingectomy or oophorectomy to complete hysterectomy and removal of the adnexa.

In cases in which the process is very extensive postoperative irradiation is advised by the author. Heliotherapy in the form of sunbaths is also a valuable therapeutic adjunct. JOSEPH K. NARAT M.D.

A Contribution to the Study of Endometriosis in Mexico (Contribución al estudio de la endometriosis en México) MARIO MADRADO BARAURI. *Ginec. Obst. México* 1948 3 13.

The author reports his work on endometriosis during the past 2 1/2 years as chief of a large gynecological service. He reviews the terminology and classifications of Sampson of the American school, and of Calatroul in Argentina who represents the German school.

The author is of the opinion and proposes that the classification of endometriosis should be (1) primary, for the lesions localized in the wall of the uterus and having anatomic continuity with the normal endometrium and (2) secondary for all lesions localized outside of the uterus and without continuity with the normal endometrium.

His statistics have been gathered from 1,483 laparotomies for gynecologic diseases. Thirty cases are listed statistically. The history symptoms pathology diagnosis and treatment of endometriosis are discussed.

It is to be noted that there were no deaths in this series, and no recurrences in the group some of the cases having been followed for 2 years.

W. FOSTER MONTGOMERY M.D.

Surgical Treatment of Rectal Complications of Radiotherapy for Cancer of the Uterine Cervix: Possibilities of Sympathetic Surgery (Tratamiento quirúrgico de las complicaciones rectales de la radioterapia para el cáncer de colútero. Posibilidades de la cirugía simpática) M. DARGENT and L. EICHLER. *Lyon chir.*, 1948, 43 199.

The serious rectal complications consist of the rectitis syndrome due to craterlike ulceration of the anterior aspect of the rectal ampulla 5 cm. above the anal canal or to inflammatory stenosis with thickening of the entire rectal wall or its anterior half. The syndrome of established stenosis which is annular, fibrous, and generally well tolerated and a rectovaginal fistula which may follow the phase of acute stenosis and is located from 4 to 6 cm. above the anal canal. These complications do not necessarily follow one another although the more grave rectitis results in stenosis or fistula there is annular stenosis which has developed insidiously. The complications may be associated with stenosis at the rectosigmoid junction or along the colon and lesions of the rectovaginal wall, the rectal sheath and mucosa, or the lymph nodes.

Some of the rectal complications are due to technical deficiencies (turning of the colpostat, slipping of the intrauterine tubes excessive roentgen treatment of the perineal area) others are due to radionecrosis of the pelvic tissues favored by infection and previous surgical trauma.

The authors found that the association of artificial anus and chemical or surgical section of the lower left sympathetic chain affords temporary or permanent relief to patients with grave perirectal syndromes that an artificial anus alone is effective in 80 per cent of these patients, and that the formation of a rectovaginal fistula itself generally results in spontaneous disappearance of the pains. This raised the question whether the operation on the sympathetic chain alone would be sufficient and nullify the need for an artificial anus. Five serious cases in which unilateral or bilateral low lumbar sympathectomy was performed are reported.

Early results showed that this intervention had modified the threshold of pain but had not suppressed it completely. The passage of the old and hard fecal masses produced enough trauma to awaken the pain but normal defecation even of very solid material did not cause pain subsequently. This sedation was demonstrated by digital examination of the rectum which became possible at the end of the first week and revealed definite softening of the walls. In 3 of the cases a rectovaginal fistula formed from 5 days to 1 month after the operation and could be attributed only to the softening of the tissues. This was particularly clear in a case of pre-existing fistula which was obliterated by a cardboardlike block and exuberant granulations of rectal mucosa. It became manifest on the fifth day after the passage of feces.

Three months after the appearance of the fistulas the stenosis had completely changed the exuberant granulations and the perirectal induration had disappeared and the fistulas opened onto a supple annular atresia which admitted the index finger. Radical operation then was successfully carried out on the fistulas.

Evidently there are mixed radionecrotic and cancerous stenoses in which reversibility is out of the question and it is probable that in these cases sympathetic surgery may show a good temporary result but an artificial anus will soon become necessary because of the inevitability of the patient reveals that conclude if observation of the infiltration of the sympathetic chain is sufficient to obtain results, the surgeon must be satisfied with it and reserve surgery for the cases in which success is only temporary the pains become intolerable and intestinal obstruction occurs.

RICHARD KEMMEL, M.D.

Torsion of Uterine Adnexa and Acute Abdominal Syndrome (La torsione degli annessi uterini nel quadro dell'addome acuto) BRUNO PARIBIO. *Ginec. Obst.* 1948, 55 1.

Five cases of torsion of the normal female adnexa are reported. In 2 patients it occurred during pregnancy.

nancy and in 3 after the period of pregnancy. In 4 the torsion occurred in the abdomen and in 1 within the sac of a femoral hernia. Two were located on the left, and 3 on the right side. In each instance the torsion produced very acute symptoms. In 1 case the diagnosis of the referring physician was ectopic pregnancy; another abdominal colic of unknown origin; in the third strangulated left femoral hernia; and in the 2 last cases, acute appendicitis.

The gynecologic examination proved very valuable for the correct diagnosis.

In some instances of this type the torsion may subside spontaneously or it may recur. Occasionally a spontaneous amputation of the twisted organ may take place.

An early operation is indicated as soon as the diagnosis of torsion has been made.

As to the mechanism of torsion the author believes that anatomic conditions serve only as predisposing factors and that the functional disturbance of nerves and blood vessels is mainly responsible for the occurrence of the condition.

JOSEPH K. SARAT, M.D.

Meigs' Syndrome (Le syndrome de Meigs). P. FRANK BAERTSIO. *Gyn. obs. Præ.* 948, 47, 50.

The author reports the case of a thin, tall, and dyspeptic woman of 66 years, who had an effusion occupying half of her right pleural cavity and an ascites in which a large ovarian tumor floated. The diagnosis of Meigs' syndrome was made and confirmed at operation. The tumor which belonged to the right ovary and weighed 300 grm. was removed and recovery was uneventful. The ascites did not reappear after the operation, and the pleural cavity which had been punctured 3 days previously did not contain any trace of fluid 11 days after the intervention. Histologically the tumor was an ovarian fibroma with myxomatous changes and partial fibrinoid de-

generation. Its surface did not present the slightest vegetation capable of explaining the ascites.

Despite its relative rarity (46 published cases) the syndrome constitutes a clinical entity which should be well known. Systematic search for a pleural effusion in cases of ovarian tumor with ascites will aid in the diagnosis. The absence of blood or of tumor cells in the fluid obtained by pleural puncture will allow correcting the diagnosis of vegetating ovarian tumor with pleural metastasis which may have been made and will completely change the prognosis. Of additional diagnostic interest is the fact that the pleural effusion occurs very frequently on the right side among the 46 published cases: the hydrothorax was on the left side in 5, bilateral in 9, and on the right in 31. As often observed, the present case began with pleural effusion which because of its tendency to recur alerted the attending physician. The rapidity and abundance of its reproduction constitute an important sign of the syndrome.

The ovarian tumor is rarely the size of that found in the author's patient. It may not exceed the size of a nut and is then discovered only during the operation after the surgeon has evacuated the ascites.

The association of ascites with ovarian fibroma is frequent. It occurs in 50 per cent of the cases. This is far from the rarity of the syndrome of Meigs. The question arises why ovarian fibroma is accompanied by ascites while uterine fibroma is not? Some authors have attached a real pathogenic value to the secretion of the cubical epithelium which covers the ovarian fibroma. This theory is alluring but does not solve the second problem: why is the fibroma associated with ascites and hydrothorax? This association is not a coincidence: there is here a relation of cause and effect as removal of the fibroma eliminates at the same time the ascites and the hydrothorax. Unfortunately the pathogenic problem of the remote action of ovarian fibroma on the pleural serosa remains unexplained.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Double Ectopic Pregnancy in One Tube DYRE TROLL. *Acta obst. gyn. scand.*, 1948 47 395

A case of double pregnancy in a single tube is presented. The patient had a fairly typical history of ectopic gestation although the diagnosis was some what difficult to make. Approximately 6 weeks after the onset of her symptoms the diagnosis was af firmed by operation at which time the right tube and a portion of the right ovary were removed.

On pathologic examination there was marked en largement of the fimbriated portion of the tube with a small area of rupture. Microscopic examination confirmed the presence of a pregnancy in this area. The isthmus of the tube was likewise distended but there was no evidence of rupture present. On microscopic examination this area was found to con tain chorionic villi.

It is stated that there were approximately a hun dred similar cases reported in the literature. Several factors might account for the difference in the size of the pregnancies, one being superfecundation and another being the local conditions of growth which may permit one portion of the tube to grow more rapidly than another portion.

Fifty Four Deaths Occurring in Pregnant Patients Who Had Hypertension ROBERT A. ROSS, S. S. LAMBERT, W. L. THOMAS, and F. B. CARTER. *Am J Obst.* 1948 55 591

The authors' article is based on an analysis of charts and records (from Duke Hospital, Durham, North Carolina) of 54 patients who had blood pressures above 140/90 and who died during pregnancy or in the immediate puerperium. The purpose of this study was twofold: first to select facts from the records which would be helpful in estimating the prognosis of similar cases in the future; second to analyze and consider the different methods of man agement as a guide to future therapeutic approach in hypertensive patients.

The steady increase in the relative importance of hypertension in pregnancy as a cause for maternal mortality is in keeping with the increase in chronic vascular renal disease as a cause of death in the gen eral population.

The elevated blood pressure was the one common denominator in all of the patients. Other factors varied considerably so that it was impossible to clas sify the exact pathologic process. The authors learned that no single factor is of great practical im portance and that the seriousness of the whole clin ical picture should be considered in the management of hypertensive patients. They believe that help from all sources is important and the simpler labora tory tests are worth while.

The fate of the infant is a most important consid eration in any pregnancy and particularly so in pregnancies involving such sacrifices as those pre sented in the study. Only 17 of 58 infants survived the neonatal period, which is not a fair ratio for the risk of 58 (maternal) lives.

The hypertensive woman with an enlarged heart, albuminuria, and in whom changes in the optic fun di have occurred, has a poor prognosis when preg nant. Serious consideration of interruption of the pregnancy by the most conservative means should be given in such cases regardless of the stage of preg nancy and contraceptive measures should be sug gested.

JOHN R. WOLFF, M.D.

Nonsegmentation of the Nucleus of Neutrophil Granulocytes in Toxicoses of Pregnancy (Sull' inserimentazione del nucleo dei granulociti neutrofili nelle tossicosi gravidiche) UMBERTO BRACALE. *Arch. ostet. ginec.*, 1948 53 31

This study was made on 20 subjects, of whom 12 had eclampsia (10 during pregnancy and 2 in the puerperium), 6 pre-eclampsia, and 2 premature toxic detachment of the normally inserted placenta. In all patients before delivery a red and white blood cell count was made as well as a differential count of the neutrophil granulocytes with segmented nucleus and nonsegmented nucleus, the eosinophils, mast cells, lymphocytes and monocytes. In addition in each formula the neutrophil coefficient of nuclear nonsegmentation of Mas y Magro was calculated by dividing the number of nonsegmented neutrophils by that of the segmented neutrophils, the normal value being between 0.03 and 0.06. Similar studies were made on the subjects 3, 5, 7, and 10 days after delivery.

The first fact observed was the increase of the non segmented forms with a Mas y Magro coefficient generally above normal. In only 6 cases were about normal values found. In pregnancy there is a leuco cytosis and generally a deviation of the granulocytes to the left. Those who have studied the percentage variations of nonsegmented neutrophils during preg nancy have found differences ranging up to 10 per cent in the absence of puerperal complications. Therefore it should be remembered that as a result of pregnancy itself there is an increase in the rate of nonsegmented neutrophils, the origin of which is probably connected with the leucocytosis of preg nancy. However if in the picture of leucopoietic hyperactivity it is possible to explain an increase in the segmented forms it is more difficult to interpret 4 cases in which persistent peripheral leucopenia was opposed to a progressive increase of the nonseg mented granulocytes. In addition some segmented and nonsegmented granulocytes in 2 of these cases showed nuclear vacuoles and pyknotic chromatin condensation. Undoubtedly in these cases (eclampsia)

sis in the puerperium) the blood picture indicates a myelotoxic condition with degenerative cellular damage of the maturing elements.

In other cases, besides the increase in the rate of nonsegmented elements, there was a leucocytosis which has remained nearly unchanged in successive examinations while the nonsegmented neutrophils decreased.

Only 3 cases presented very high rates of nonsegmented neutrophils with a May & Magro coefficient up to 0.97. These were cases of severe infectious complications in which the leucocytosis ran high. Therefore the infective state, in addition to the toxicosis of pregnancy, must be taken into account. In these cases, 2 of which were subjected to vaginal intervention and 1 to cesarean section which was followed by a large suppurating hematoma, a massive introduction of immature elements into the circulation must be accepted rather than an inhibition of maturation by the toxicosis of pregnancy.

RICHARD KEMPEL, M.D.

LABOR AND ITS COMPLICATIONS

Protrusion of the Acetabula as a Complication of Labor. JENS PETERSEN, *Acta radiol. Stockh.*, 1948, 39, 205.

The author discusses the etiology of protrusion of the acetabula and presents a case in which this condition resulted in prolongation of the parturition and delivery in a 32 year old primipara. The course of the parturition, even for the patient's age, was rather protracted (about 45 hours). The roentgen examination revealed the fetus in cephalic position. The head showed evidence of accommodation and a rather large segment was seen below the pelvic inlet. There was bilateral distinct protrusion of the acetabula, with projection into the pelvic lumen of about 1 cm. on the right side and a little less on the left. The pelvic measurements (by the simple geometric method) were anteroposterior diameter 7.9 cm, right oblique diameter 11.9 cm., left oblique diameter 12.9 cm., transverse diameter 9.1 cm., and the smallest distance between the acetabula, 10.2 cm.

The skull of the child revealed pressure traces which suggest that the protraction was due to protrusion of the patient's acetabula.

FRANK L. HUNNEY, M.D.

The Fate of the Living Viable Babies in Extrauterine Pregnancies. MAX RUTER and CHARLES WICKER, *Am. J. Obst.*, 1948, 55, 489.

This article was written with the idea of determining as nearly as possible from the limited clinical material available at the Charity Hospital of Louisiana, New Orleans, and from a survey of the literature the fate of the viable babies delivered from extrauterine pregnancies. Only cases of infants born living after 28 or more weeks of gestation were selected.

Forty-one cases are tabulated from the literature to supplement those previously summarized. Four

new cases of extrauterine pregnancies with living, viable babies are reported from the Charity Hospital of Louisiana. Their case histories are abstracted.

Only about one-fourth of all the extrauterine pregnancies diagnosed after the fifth month of gestation will result in viable living babies. About one-third of all these living viable babies will have major or minor deformities including those which were incompatible with life and approximately half will survive 3 days or more.

JOHN R. WOOTY, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Early Rising after Delivery. EDWARD L. CORNELL and JOSEPH J. MILLER, *Am. J. Obst.*, 1948, 55, 768.

On thousand patients at the Menorah Hospital, Chicago, Illinois, were allowed up on the sixth postpartum day or earlier. Eighty per cent of these patients were allowed up prior to the fifth day and 30 per cent were allowed up prior to the third day. Fifty-three of these patients had a cesarean section. The remainder had vaginal deliveries with the usual incidence of operative procedures.

These patients were apparently in much better condition at the time of discharge than if they had remained in bed for 8 or more days. The patients expressed a sense of well-being and a feeling of general good health earlier than those allowed to remain in bed for a longer period. They were in a position to adapt themselves more readily to their daily household routine.

Wound healing following episiotomy was not adversely affected nor was the morbidity increased. Urinary retention did not occur in any case, and postpartum cystitis and pyelocystitis were at a minimum, 3 cases being established by clinical and laboratory methods. No case of thrombophlebitis occurred among the patients delivered vaginally. The rate of involution of the uterus was increased. No case of uterine prolapse occurred.

The postoperative course following cesarean section was more nearly uneventful. Distention was infrequent. The necessity for catheterization and enemas was lessened when the patient was up to the toilet on the first postoperative day. One case of thrombophlebitis occurred in this group.

The authors believe that early ambulation is of distinct benefit in the immediate postpartum period. When necessary because of overcrowding the patient may be discharged from the hospital earlier than heretofore with a greater margin of safety. The authors express a caution as to the possible late gynecological complications of this early ambulation, such as prolapse and relaxation.

JOHN R. WOOTY, M.D.

Immediate Postpartum Hemorrhage Due to Retained Secondaries. B. H. CARROLL, H. H. MERRILL, and O. H. STONE, *Am. J. Obst.*, 1948, 55, 620.

Excessive blood loss in the third stage of labor is the forerunner and the cause of much of our maternal mortality and morbidity. The authors believe that

the most frequent cause of postpartum uterine bleeding is faulty separation or retention of parts of the secundines. The purpose of this article is to record the blood loss the clinical course and the treatment of 115 private patients in whom retained placenta membranes or both was the cause of the hemorrhage. The method and apparatus used in collecting blood is described.

The customary method of estimation is notoriously deceiving and inaccurate. Accurate measurement of blood loss may be used as an early objective sign which sharply identifies the condition of the patient and also justifies early removal of retained tissues to control uterine bleeding. When 500 c.c. of blood have been collected the patient is in the abnormal or danger zone, there being an associated increased number of clinical complications. With one exception the morbidity mortality shock, and need for chemotherapy occurred in patients who had lost more than 500 c.c. of blood. Moreover blood loss over 500 c.c. was associated with a decreased ability of the mothers to nurse their infants.

Retained tissue was the cause of the immediate postpartum uterine hemorrhage in all of these cases. Early manual removal of this retained tissue permitted normal contraction of the uterus and arrested hemorrhage. The authors describe their method of manual removal of tissue. Manual invasion of the uterine cavity was not associated with a high incidence of morbidity. It is believed that infection is more likely to develop in cases in which retained pieces of tissue are left in the uterus.

A real and noticeable clinical response was observed when the blood loss was promptly replaced. Thirty three per cent of the patients were transfused. It was the authors' opinion that more transfusions could have been given with benefit. The therapeutic action is both prophylactic and curative.

JOHN R. WOLFE, M.D.

Motor Difficulties of Neurological Origin following Delivery (Troubles moteurs d'origine nerveuse consécutifs à l'accouchement.) J. BRETT *Rev f gyn obsi* 1947 42 354.

After reviewing the French literature on nerve injuries occurring in pregnancy or following delivery, the author reports 3 such cases. All 3 patients had difficult forceps deliveries and upon awakening from anesthesia complained of pain in one or both legs. Neurological examination revealed pain, sensory nerve disturbances, muscle weakness, absent or impaired reflexes and foot drop.

Analyses of the type described have a sudden onset. As a general rule the patient is anesthetized for an operative delivery. Upon awakening from anesthesia, she complains of weakness, although this may not be noted until she attempts to walk. These paralytic are the results of injury to the external popliteal nerve, the internal popliteal nerve or the roots common to these two nerves.

The end results are variable. In most cases recovery is favorable and rapid. In certain cases

however convalescence is prolonged and weakness and foot drop may persist for years.

In these 3 cases and in those reported in the literature prolonged labor late engagement at the end of dilatation and a difficult forceps delivery were the usual story. The author discussed the dangers of applying the posterior blade of the forceps at the level of the promontory.

Injuries to the lumbosacral trunk or to the nerve itself may result from prolonged pressure by the fetal head mechanical injury by the forceps blade pressure from extravasated blood or compression by scar tissue.

The usual treatment consists of electrical stimulation and the administration of vitamin B. If a similar case should occur the author intends to resort to rapid surgical intervention to decompress the nerve by incision of the pelvic aponeurosis.

CRATO W. MUCKLE, M.D.

NEWBORN

Dry Gangrenes of the Newly Born (Les gangrènes sèches du nouveau-né) L. CLIMEX and J. BRETT *Gyn obsi*, Par., 1948, 47 304.

The authors report a case of spontaneous amputation of the two lower extremities which began during the immediate postnatal period and presented the following similarities with previous descriptions of cases and with classical concepts of the disease. The lesions were bilateral, the clinical evolution was toward elimination of the involved tissues and there was complete absence of deleterious repercussion in the general condition of the patient. However the extent of the involvement was particularly serious as it ended in elimination of the two legs while in other reported cases of involvement of the extremities the lesions often involved only the skin and part of the subjacent soft tissues, allowing attempts at surgical repair. The notable fact about the case was that the authors were able to observe the beginning and the partial regression of the primary lesions which appeared about 24 hours after birth when the base of the trunk, the prepuce and the scrotum became the site of cyanotic plaques which disappeared later. In the lower extremities the cyanosis was localized to a segment having the form of a cuff below which there was absence of circulation with lividity but without cyanosis. The stage of phlyctena which was most frequently observed by other authors appeared only several days later in this case.

At about the same time the authors also observed 2 newborn infants with local loss of substance of the scalp which was in the course of healing at birth. These 2 cases seemed to present minor forms of the ulcerous disease with an intrauterine beginning described by Ombrédanne and Lacassie.

The pathogenesis of these accidents is not clear. The classical role played by amniotic cords so often incriminated must be rejected while an infectious origin is out of the question. Traumatism in the course of delivery has been accused without factual

basis. The most probable cause seems to be vascular impairment. The authors have made various sections of the eliminated segments of extremities and found discrete vascular lesions, dilated veins but no thromboses, intact arteries, and absence of the popliteal artery. In connection with the latter it is possible that this arterial segment was missing congenitally, but then why should the disturbances have occurred only after birth? It would seem that the hypothesis advanced by Fèvre corresponds best to the observed facts (there may have been a primary local impairment of the capillaries with resultant local ischemia and a secondary extensive process). Perhaps an important role in these accidents should be attributed to the sympathetic nervous system.

RICHARD KEMPEL, M.D.

MISCELLANEOUS

Maternal Measles, Mumps, and Chickenpox as a Cause of Congenital Anomalies. M. J. FOX, E. R. KRUMHOLTZ, AND J. L. TERRELL. *Lancet* Lond., 1945, 746.

The association between the contraction of rubella by the mother in early pregnancy and the development of congenital defects in the offspring is discussed. GREIG (1941) reported 75 such anomalies in Australia, and SWAN (1943, 1944, 1946) reported 101 similar cases in Australia. Since then, many reports have accumulated.

The most common defects noted were cataracts, heart disease, deaf-mutism and dental abnormalities. Others were microcephaly, microphthalmos, harelip, cleft palate, pyloric stenosis, spina bifida, mongolism and nevus.

SWAN (1944) suggested from his findings that 100 per cent of women contracting rubella in the first 3 months and 50 per cent contracting it in the third month would have defective children. These workers as well as others did not cite the number of women with rubella whose offspring had no congenital defects.

The question is raised whether other infectious diseases, particularly those due to a virus, may cause similar defects. Except for the work of AYCOCK and INGALLS (1946) with poliomyelitis the authors found no report dealing with numerical probability of anomalies following maternal virus diseases other than rubella. Of 131 pregnancies associated with poliomyelitis which were studied by Aycock and Ingalls 33 ended in abortion, miscarriage, stillbirth or death of the infant shortly after birth. Of the remaining 98 children, one had clubfoot and another heart disease; their mothers having had poliomyelitis in the second and third months of pregnancy respectively.

The present study was undertaken to determine the numerical probability of anomalies in children born of mothers who had measles, mumps, or chickenpox in pregnancy. These diseases were chosen because each is caused by a filterable virus, each is common, and in Milwaukee each is legally notifiable to the Health Department.

In the 4 years from 1942 to 1945 there were 18,817 cases of measles, 14,014 cases of mumps and 26,333 cases of chickenpox, with the reports showing 31% in 100 cases of measles, 356 cases of mumps and 77 cases of chickenpox.

Public health nurses visited all of the patients, so were available; many had moved because of the war or housing shortage. Only 54 per cent of the married women with measles, 70 per cent with mumps, and 65 per cent with chickenpox were located and interviewed. Dental defects were not included and questionable degrees of mental retardation were not recorded. Such congenital abnormalities as cataract, deafness, heart disease, cleft palate and harelip were specifically investigated. Each child reported to have a congenital defect was examined by one of the authors. Many defects were found to be acquired and not congenital such as otitis media and rheumatic heart disease.

Of the married women 346 had had 580 children before they contracted any of the three diseases; 6 of these children had congenital defects. These same women had 90 live children after recovering from the virus disease. Of this number 33 had been born of pregnancies associated with one of the three virus diseases. The remaining 76 children had been born of pregnancies which had begun after the mother had recovered from one of these diseases. There were no anomalies among the 76 children.

The number of children born to mothers who did not have any of the virus diseases during pregnancy was 330 plus 76 or 665. Of this group 6 had congenital anomalies; a normal incidence of 0.9 per cent.

Of the children born to 33 mothers with measles, mumps, or chickenpox during pregnancy only one had a congenital anomaly. There were no defects in 22 children born after the mother had had mumps, and none in 4 children born after the mother had had chickenpox. Of the 7 children born after maternal measles, one had a unilateral harelip.

In the case of mumps, 3 children were born after mumps in the first 3 months, and 7 after mumps in the third and fourth months with no defects. With chickenpox none were born after the disease in the first 3 months and only 2 after the disease in the third and fourth months with no defects. The only anomaly in the series occurred after measles in the fourth month. The only child born following measles in the first 3 months had no anomaly. No anomalies occurred in 8 babies born of mothers having had measles, mumps or chickenpox in the first 3 months of pregnancy.

The authors state that the development of anomalies in babies born of mothers who have had virus diseases in pregnancy deserves serious study because of the handicap these serious defects impose on the individual and the economic burden on the parents and the community.

From the reports of FOX and BORTON (1946) and AYCOCK and INGALLS (1946) the numerical incidence of anomalies in 25 children born of mothers having rubella in pregnancy was 2 or 13 per cent. In another

series by the same authors 2 of 12 infants or 17 per cent, had anomalies. In the authors' report, 1 child with an anomaly was found following 7 cases of measles in pregnancy a rate of 14 per cent. The statistical study but does show the need of carefully conducted investigation.

The true numerical incidence is difficult to determine because the cases in which mothers with virus disease give birth to offspring with congenital defects are reported, whereas those in which these mothers do not have defective infants are not reported.

BYRORD F. HASKETT M.D.

Benign Trophoblastic Cell Proliferation. C. G. TEDESCHI and A. A. MATARAZZ. *Am. J. Obst.*, 1948, 55: 758.

Trophoblastic cells often invade the uterine wall in a normal pregnancy. Whenever this invasion occurs two possibilities may be present: benign trophoblastic cell hyperplasia, or a form of chorionepithelioma. Since the differentiation between these two conditions is based quite often on a matter of opinion rather than definite histologic criteria, need of less radical treatment may be recommended and many uteri are sacrificed needlessly.

In the differential diagnosis between benign trophoblastic cell proliferation and chorionepithelioma, it is believed that valid information can be obtained from the intimate structure of the cell type, mainly involved in the proliferative process. On the basis of cytologic criteria two patients were treated in a conservative manner. The final outcome proved this judgment to be correct.

The distinction between this benign and malignant condition should be based not on the invasive character of the trophoblastic type structure but entirely on the morphologic character of the malignant cell.

JOHN R. WOLFF M.D.

Factors in the Treatment of Chorionepithelioma. ALBERT W. HOLMAN and ELIZABETH H. SCHWENK. *Am. J. Obst.*, 1948, 55: 639.

Confusion exists in the minds of many physicians with regard to the relation between hydatid mole and chorionepithelioma. This is due in part to vague and misleading pathologic classification. The authors

believe that the classification of chorionepithelioma should be clarified that the word chorionepithelioma should be discarded and that chorionepithelioma grades 1 to 4 should be used to replace it. Chorionepithelioma is a malignant change of the trophoblastic tissue both the Langhans' and syncytial layers may be involved.

Hydropic degeneration can occur in the chorionic villi of any pregnancy and is responsible for many abortions. For this reason alone the uterus should be curetted in every patient in whom a miscarriage occurs in the first trimester of pregnancy and the curettings should be examined microscopically so that the early abortion of a hydatid mole will not be overlooked and a beginning chorionepithelioma may not be unsuspected.

Every patient who passes a hydatid mole must be suspected of harboring a chorionepithelioma. After a woman has passed a mole she should be curetted immediately and the curettings should be examined. Negative findings from curettage mean nothing and the urine of the patient should be examined for chorionic gonadotropic hormones by the Friedman test at intervals, until a year has intervened since the passing of the mole.

The primary, the most frequent, and the cardinal symptom of both hydatid mole and chorionepithelioma is bleeding. Any bleeding during pregnancy or other signs of threatened miscarriage must cause the thought of hydatid mole to be borne in mind. Likewise any bleeding following miscarriage or pregnancy must cause chorionepithelioma to be suspected.

The ultimate clinical diagnostic method for chorionepithelioma is the biologic pregnancy test and if this test is positive 2 weeks following pregnancy or the passage of a mole, hysterectomy should be performed in the absence of palpable lutein cysts. Roentgen examination of the lungs should always precede hysterectomy for chorionepithelioma because pulmonary metastases are frequently present before they are suspected and if recognized early may be treated by roentgen radiation. The ovaries should be removed only when involved by the primary growth, or by metastases. The vagina and vulva should be examined carefully before hysterectomy is carried out because metastases to the vagina frequently occur very early.

JOHN R. WOLFF M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Unusual Case of Adrenal Carcinoma. L. R. BROTTEN AND JOCKEY PATTERSON. *Brit. M. J.* 943, 751

The authors reported a case of adrenal carcinoma because it showed the general clinical appearance of typical group 1 virilism and in the later stages manifested disturbances in the carbohydrate and steroid metabolism of a particularly striking order.

Furthermore this case afforded an opportunity for the successful application of a newly devised urinary color test for distinguishing between adrenocortical carcinoma and marked adrenal hyperplasia.

A test of malignancy the potentialities would seem to be not less than those of such acknowledged diagnostic aids as the gonadotropin assays for chorionic thecoma and the serum and phosphate excretion in prostatic carcinoma. ROBERT TRENKLE, M.D.

Massive Hydronephrosis. HOWARD A. HOFFMAN. *J. Urol. Balt.* 943, 59-784

The author presents reports of the cases of massive hydronephrosis seen in the Massachusetts General Hospital, Boston, from 1921 to 1946 inclusive. Because of the relative asymptomaticity of the disorder the frequent failure to consider it in the differential diagnosis of abdominal masses, the ever-present danger of rupture and shock, the frequent ill-advised performance of laparotomy and the high incidence of mortality it was felt that a review of the entire subject was indicated. A review of the literature revealed that the total number of reported cases by the beginning of 1947 was 69, and of these a very substantial percentage were misdiagnosed. It is the author's impression that these cases are not as rare as the reports in the literature would seem to indicate during the period studied 10 cases of massive hydronephrosis were found, an incidence of approximately 3 per cent of all hydronephroses admitted to that hospital in that 6 year period. From this study it was found that the incidence extended through all age groups. Most patients however were in the second, third, and fourth decades.

Four of the patients complained of ache in the flank or loin. Of the remaining 6 a came in with gastrointestinal symptoms thinking they had peptic ulcer. One came in without any symptoms to have a routine check-up for hypertension and appeared with leg and groin pain from thrombophlebitis, and the last was concerned because her clothing kept feeling tight despite repeated letting-out.

On physical examination one-half the patients had a palpable mass in the flank, and that without tenderness. Of the remaining 3, 1 had costovertebral angle tenderness but no mass, and 3 gave an entirely negative physical urological examination.

Six of the 10 patients had essentially negative urine. Of the remaining 4, 2 had pyuria alone and

the other 2 had both hematuria and pyuria. Three of the infections were associated with the *Bacillus coli* and one with the *Bacillus pyocyaneus*.

Except in 1 patient with ureteral calculus, the intravenous pyelogram in no instance gave the diagnosis of massive hydronephrosis. In 6 cases it disclosed only a nonfunctioning kidney. The retrograde pyelogram, however, led to the urologic diagnosis of massive hydronephrosis in 9 of the 10 cases. In this series 9 of the 10 cases had involvement of the left side. There is no definite reason for this, and other authors have claimed that the involvement occurred with equal frequency on both sides. Without urologic study the true diagnosis was not made in any instance. The reasons for definitive surgery were not included in this report, however, in one instance it was the considered judgment of the surgeon that plastic measures were not feasible and nephrectomy had to be carried out. In 2 cases permanent nephrostomy had to be done as the kidney was a congenitally solitary one.

The massive hydronephrosis was associated with distinct obstruction of the ureteropelvic junction in 3 aberrant cases 2 of the 10 cases. In 3 cases organic stricture of the ureter or junction without aberrant vessels as demonstrated. The kidney destruction was associated with ureteral calculus in 1 case. In 4 cases no obstruction was demonstrable.

It is agreed by most authors that the large majority of massive hydronephroses are congenital in origin. They can attain a large size and remain asymptomatic only when infection is absent. Uncomplicated hydronephrosis then is notoriously well attended by specific symptoms. Thus the patient does not present himself to the urologist and many cases will not be seen until the sac has ruptured after some abdominal injury. When this occurs the diagnosis is quite likely to be missed and laparotomy is carried out because an intra-abdominal accident is suspected as the cause of shock.

Pyelographically the condition suggests itself by a displacement of the ureter medial and to the opposite side (as in tumor). If a ureteral catheter can be passed by the obstruction the diagnosis can readily be made. Plastic repair should be considered in each case but it is not reasonable that such can often be carried out. The cortex has usually been irreparably damaged and nephrectomy must be performed. When the hydronephrosis is infected and the patient is septic a 2-stage procedure may be lifesaving.

ROBERT O. REAMES, M.D.

Recurrent Renal Calculi. JAMES C. KIRKBRIDGE AND JOHN N. FRUIT. *J. Am. M. Ass.* 943, 1371-2

The authors discussed the management of recurrent renal calculi complicating the recumbency of patients with war wounds. Only cases in which the patients were treated by operative procedures are

reported in this article. The literature on the incidence and causation of renal calculi is reviewed in some detail. The authors believe that recumbency with its attendant urinary stasis is a major causative factor of renal calculi in many militarized patients. Patients with paraplegia and with complicating vesicoureteric conditions constitute a special problem. Almost all of these patients have urological infections. It is believed that recumbency stasis and infection cause a high incidence of renal calculi. Also damage to renal tissue by infection battle injury or surgical procedures has played an important part in the recurrence of calculi.

Because calculi act as foreign bodies causing renal damage they should be removed by open surgery without undue procrastination a policy of watchful observation may be dangerous. Of the 25 patients treated by operation 12 had one previous operation and 13 had two or more previous operations. The calculi were removed from 8 patients (32 per cent) by pyelolithotomy from 3 (12 per cent) by nephrolithotomy from 7 (28 per cent) by nephropyelolithotomy from 4 (16 per cent) by calyceal resection and from 3 (12 per cent) by nephrectomy. Pyelolithotomy is the operation of choice but it is rarely possible as a secondary operation. On account of previous renal surgery, the kidneys in these patients are adherent to the adjacent structures which makes exposure difficult. The subcapsular approach reduces to a minimum the damage to the kidney and adjacent organs and therefore is the preferred operative procedure.

The authors believe that the removal of renal calculi is only one phase in the management of renal calculi and may be a misdirected effort unless there is appropriate postoperative care and thought to prevent recurrence of the calculi. The regimen for the prevention of recurrence is summarized. Roentgenologic follow-up should be carried out at 3 month intervals in order to detect early recurrence.

ROBERT TURELL, M.D.

Fig. 1 (Garcia and Rocchi) Shows the megaureter with strictures.

Megaureter Pyeloureteral Anastomosis with a Loop for Exclusion (Megaureter Anastomosis Pyeloureteral con asa excluda) A. E. GARCIA and A. ROCCHI. *Rev argent urol.*, 1947 16 153.

A woman aged 38 was admitted to the hospital with complaints of frequent pains in the right lumbar region of 2½ years duration. The attacks of pain were accompanied by fever and vomiting. The right flank was painful to palpation. The urine had an acid reaction and its sediment contained

Fig. 2 The anastomosis between the renal pelvis and the ureter

epithelial cells and the usual amount of white and red blood corpuscles and micro-organisms. Retrograde ureteropyelography demonstrated a greatly dilated right ureter with angulations. The findings were less pronounced on the left side.

Under peridural anesthesia Eckehorn a incision was made, which exposed the right kidney and the corresponding ureter in its entire length. Angulations were relieved by an extensive ureteropyelolysis but the strictures remained. A longitudinal incision was made through the renal pelvis and another through the upper portion of the ureter and both incisions were united with one layer of plain catgut number 00.

The patient made an uneventful recovery. Excretory urography and retrograde ureteropyelography in anteroposterior and oblique directions demonstrated a well functioning anastomosis.

JOSEPH K. NARAY, M.D.

Two Cases of Tumors of the Ureters. Discussion of the Surgical Treatment (Dos casos de tumores del ureter. Consideraciones sobre la terapéutica quirúrgica). ALBERTO E. GARCIA AND JOSE CARAL. *Rev. arg. urol.* 947 6, 1935.

The majority of tumors of the ureters are located at the lower end. Two such cases are reported by the author. The first patient a man 64 years of age was admitted with complaints of hematuria of 4 months duration. A papillary proliferation was found at the cystoscopic examination in the region of the left ureteral orifice. N. dye was excreted by the left kidney during the first 15 minutes after its injection. An excretory urogram showed a left pyeloureteral ectasia. A total left nephroureterectomy with partial excision of the bladder was performed. The histologic diagnosis was paramalpighian epithelial blastoma.

The second patient 50 years of age came with complaints of hematuria of 4 years' duration. The cystoscopic examination revealed a tumor at the orifice of the right ureter. Excretory urograms demonstrated a dilatation of the lower portion of this ureter. The transvesical approach was used to remove the tumor. The histologic examination revealed numerous atypical cells and many mitoses. The conservative procedure in this case was justified because the dilatation of the lower portion of the ureter was moderate while the upper portion appeared normal.

For the purpose of ureteronephrectomy the author advocates a double incision, one in the lumbar region and the other in the lower midline.

JOSEPH K. NARAY, M.D.

Urinary Calculi. HAMILTON W. MCKAY, H. HAYNES BAIRD, and KENNETH LIPKIN, JR. *J. Am. M. Ass.*, 948, 137, 5.

The authors analyzed 200 cases of urinary calculi and discussed the management of ureteral stones. Of the 200 patients, 77 had renal stones, 20 had stones in the upper part of the ureter, 12 in the mid

dle of the ureter, 90 in the lower part of the ureter and 20 in the bladder; there were 4 patients with bilateral ureteral calculi and 12 with bilateral renal calculi. The mortality rate was 0.5 per cent. Chemically the stones were composed of the following: (1) calcium carbonate, (2) calcium phosphate, (3) urates, (4) mixtures of calcium carbonate, calcium phosphate and urates, and (5) oxalate (rare).

The greatest difficulties were encountered with small rough stones in the terminal aspect of the ureter. Because of the well known difficulties, the authors devised a new ureteral open surgical technique which is described in detail. The transvesical or intravesical approach to impacted stones in the intramural part of the ureter or just back of the bladder is believed to be of value at times. The technical steps of this procedure are also briefly outlined.

In the discussion GOLDSTEIN stated that the authors had wisely and rightfully held to no conventional procedures. He believes that the surgical policies described in the article are now in practice in most of the larger clinics. Goldstein has in the past few years gradually increased the percentage of open operative procedures for the elimination of ureteral stones.

LIVERMORE, the inventor of one of the metal instruments for the removal of ureteral stones, condemned them because they are dangerous and may damage or puncture the ureter. He believes that only ureteral catheters and flexible bougies should be used.

As to the best time to operate, this depends on the condition of the patient and the judgment of the urologist.

ROBERT TURNER, M.D.

BLADDER, URETHRA, AND PENIS

Total Cystectomy for Carcinoma of the Bladder (La cistectomía total a el cancer de vejiga). RICARDO ESCOBAR. *Rev. arg. urol.*, 947 6, 20.

Poor results of a partial cystectomy for the treatment of infiltrating carcinoma of the bladder induced the author to employ a total prostatic cystectomy. The operation is not performed if metastatic adenopathies are present.

In 12 of 12 patients the ureters were implanted into the intestines and in 1 into the skin. In 9 patients a one-stage operation was employed for the implantation of the ureters into the intestines, while in 1 patient a two-stage operation was performed. One patient succumbed to the operation. In 8 patients a complete cystectomy was done without post-operative mortality. Two patients expired 1 year and 2 patient, 1 1/2 years after the operation. Of the remaining 5 patients, 3 were alive 1 1/2 years after the operation, in 1 the bladder was extirpated 20 days before this report was made and in the other it was extirpated 3 months before.

In 7 of the 8 patients, the abdominal approach was used and in 1 a combined abdominoperineal route was used.

The implantation of the ureters in the skin as a preliminary step to the extirpation of the bladder is

The fourth case was that of a woman 34 years of age who entered the hospital with an admission diagnosis of torsion of an ovarian cyst. After examination surgical intervention was advised. At operation, a retrovesical cyst was found between the layers of the broad ligament. A second one was found in the posterior layer of the broad ligament. On extension of the incision a large cyst was found on the inferior aspect of the liver.

The pelvic localization of the echinococcal cyst is never primary. It is always secondary as Deve has shown. It follows the rupture of intra-abdominal hepatic or splenic cysts. The site of the cyst may take two positions. It may be retrovesical or retrovesical and prostatic.

The superior vesical cyst compresses the bladder and causes diminished capacity with polyuria. The inferior vesical cyst causes pain on micturition and dysuria. The hydatid cysts have the same development as echinococcal cysts in other locations.

The symptoms of retrovesical cysts are polyuria and dysuria. The patient has frequent diurnal and nocturnal micturitions. The urine is rarely purulent unless a renal infection is also present.

The physical signs are certainly characteristic. The suprapubic abdominal pelvic tumor gives the impression of a distended bladder. If the cyst is vesicoprostatic, rectal examination permits the palpation of a rounded mass above the prostate. It is not possible to reach the upper limits of the mass. On rectal examination associated with hypogastric palpation one is able to obtain some impression as to the size of the mass.

Urethrocytoscopic examination, cystograms and barium enemas were used by the author to establish diagnostic criteria. The possibility of distention of the kidney pelvis and the ureter should make a renal examination advisable.

The diagnosis of hydatid retrovesical prostatic cyst is easy when it is associated with a hydatid disease background. The retroprostatic mass might suggest a prostatic abscess, but its indolence resistance that is nonfluctuant, the absence of draining pus at the urinary meatus, the ease of transverting the urethra, the absence of temperature leucocytosis, and polymorpholeucocytosis nullifies this diagnosis. If the cyst is large, a hypogastric mass produces concluding evidence of the disease. Simple catheterization will establish that the tumor is intraperitoneal rather than due to a distended bladder. Rectal examination shows a hypogastric mass, but an intra-abdominal tumor is difficult to diagnose by rectal palpation.

X-ray examination after a barium enema helps to confirm the presence of an intra-abdominal lesion.

The Casoni test is positive for hydatid cysts and helps to establish a diagnosis.

The treatment is surgical with early intervention to prevent complications of infection, rupture, and definitive renal lesions due to compression of the ureters. The therapeutic measures are the same as they are in the other locations of echinococcal cysts.

It is a question as to whether one should evacuate the cyst with immediate closure or with marsupialization of the opening. The author favors marsupialization even though the convalescence is longer as the results are better.

A suprapubic incision is made with the patient in the Trendelenburg position. The peritoneal cavity is retracted. If intra-abdominal cysts are found, they are enucleated and the peritoneum is closed. The vesical region is then exposed and two masses are seen, the superior one the cyst and the inferior one the bladder pressed against the pubis. The superior surface of the cyst is cleared and the surrounding structures are protected by formalin compresses. The cyst is punctured and the contents are evacuated. The fluid is replaced with formalin solution which is retained for 10 minutes. The cavity is curetted and all the daughter cysts and the mother membrane are removed (if possible in one piece). The pouch is marsupialized with closure of the incision about a drain. The large retrovesical cysts are more often closed without drainage and marsupialization.

In résumé the author presented 4 cases of retrovesical hydatid cysts. The existence of intraperitoneal hydatid disease in 2 of the cases seemed to confirm Deve's opinion that these cysts have an intraperitoneal origin. The physical examination and x-ray findings were presented in these cases. Sabatini advised exposure of the cyst with evacuation of its contents, lavage with formalin solution, curettage, removal of the mother membrane, and marsupialization of the edges of the sac in hydatid cysts of the pelvis.

CORRAD A. KERN, M.D.

Hemolysis during Transurethral Prostatic Resection. C. D. CARRUT *J. Urol. Med.*, 943, 59: 17

The author points out that every urologist who strives to resect the prostate gland transurethraly down to the surgical capsule knows that the operation is sometimes followed by uremia and other disturbances.

As a characteristic reaction the patient has rigors and cyanosis during or shortly after operation, nausea and vomiting often ensue and oliguria and azotemia may soon appear.

A mild, nonobstructive jaundice and an anemia more severe than would be expected from the loss of blood are typical reactions. Hypertension may occur later.

Since the type of uremia the author discusses seems to occur most often when considerable blood has been lost during or after operation the azotemia might be attributed to the spasm of the renal vessels. While this condition explains some of the features of the obscure uremia which may follow transurethral resection it does not account for the mild, nonobstructive jaundice which usually accompanies it, nor does it account for the fact that an anemia out of all proportion to the amount of blood lost by hemorrhage is often demonstrable as early as 24 hours after operation.

Emmett suggested that this phenomenon was due to the sterile water used as an irrigating fluid during transurethral prostatic resection. The sterile water may enter the prostatic veins producing hemolysis and damaging the kidneys as these organs are involved when transfusion with incompatible blood is done.

Wardill concluded that the anemia following prostatic operation was identical with that following the crush syndrome or the transfusion of incompatible blood.

Drisk hemorrhage requires the use of large quantities of irrigating fluid at high pressures to permit the operator to see more clearly. When the operation is prolonged conditions are then favorable to be molytic. Inability to predict if a hemolytic reaction will occur may be due to the variations in the size and number of the openings made in the prostatic or periprostatic veins and the variations in the size of the veins.

The author reported the case of a man who was operated upon May 28 and expired June 9 of hemolysis following a transurethral prostatic resection. The autopsy findings showed postoperative hemoglobinemia, obstruction of the renal tubules by pigmented casts and toxic changes in the tubules with hypertrophy and dilatation of the heart from chronic passive congestion of the liver, cholelithiasis and ascites (from peritoneal lavage). The microscopic sections of the kidney were identical with those from another patient who had anuria following the transfusion of incompatible blood.

The author reviews the literature on renal insufficiency following transfusion of incompatible blood. Similar changes have been found in the kidneys after traumatic muscular ischemia, heat stroke, sulfonamide intoxication and poisoning with certain vegetable and chemical agents. Lucke has suggested the term "lower nephron nephrosis" for renal lesions of this nature. The changes in the kidneys in these conditions include vacuolization, necrosis and desquamation of the epithelium of Henle's loops and the distal convoluted tubules. Pigmented casts are found in Henle's loops in the convoluted tubules and in the collecting tubules. Hemosiderin granules are seen in the convoluted tubules. Edema and cellular reaction are found around the more severely damaged tubules. Precipitated protein may be found in the glomerular capsules which are not dilated although the tubules proximal to the casts may have dilated lumina and thinned epithelium.

It appears from experimental work that alkaline hemolytic reactions since death usually follows renal failure.

It would seem that the deleterious effects of transfusions with incompatible blood are due to the transport to the kidneys of hemoglobin or one of its breakdown products which damages the renal tubules either by some direct toxic action, by the production of vascular spasm by plugging of the nephron or

perhaps by all three of these factors. It has been further suggested that the oliguria that accompanies these lesions is due to unselective absorption of the glomerular filtrate by the injured tubules. If hemoglobinemia alone is to damage the previously normal kidney it must be of a severe type.

Sterile tap or distilled water is usually used as an irrigating fluid in transurethral prostatic resection. If the operation is reasonably complete, many good sized veins in the operative area are opened. The resulting hemorrhage necessitates running the water usually under considerable pressure to keep the field clear, so that the operator may be able to see the bleeding points and secure them by hemostasis. The irrigating water now containing blood already hemolyzed in the bladder may enter the venous system and thereby produce hemolysis.

Investigative work has shown that the plasma hemoglobin averages 3.08 mgm. per cent before and 45.4 per cent after the operation. In 3 of 8 patients who developed mild oliguria, elevation of the urea nitrogen and disproportionate anemia in addition to mild jaundice was seen. The postoperative plasma hemoglobin averaged 81 mgm per cent. This would further support the view that hemolysis occurs during transurethral resection.

The treatment of the patient with severely damaged kidneys as a result of hemoglobinuria is concerned mostly with keeping him alive until natural healing processes within the kidneys can take place. Oxygen therapy seems indicated in the initial stage for vasospasm probably damages the tubules by reducing the oxygen supply.

The most accurate method of following the fluid balance in the oliguric patient is by accurately ascertaining his daily weight and giving no more fluid than is required to keep that weight constant or allow it to fall slowly.

The acidosis which usually accompanies uremia must be controlled by the administration of alkalies without overloading the patient with sodium or producing an alkalosis which may further impair the renal function. The anorexia may require tube feeding and the administration of parenteral vitamins in the early stages. Nasal suction may control nausea and vomiting. Parenteral replacement of proteins may be required and the anemia resulting from blood loss and hemolysis may demand transfusion. Peritoneal lavage may relieve the body nitrogenous waste until the kidneys resume effective function.

The solution to the problem of hemolysis following transurethral prostatic resection lies in its prevention rather than the treatment of the ensuing hemoglobinuria. The use of irrigating fluid under the lowest possible pressure that will allow the operator to see clearly is important. In order to prevent hemolysis an irrigating solution that does not hemolyze blood should be used. Saline solution or other inorganic salt solutions cannot be used because being good conductors of electricity they diffuse the current from the electrode which prevents satisfactory cutting and coagulation.

The author used 4 per cent glucose solution as an irrigating medium without hemolytic reaction. He warns that care should be taken when this solution is used in diabetic patients.

In summarizing the author states that intravascular and intravascular hemolysis may be produced during transurethral prostatic resection by the water that is used as an irrigating fluid. Hemoglobinemia probably does not harm the kidney unless the hemolysis is very severe or the kidney is simultaneously damaged by vasospasm from excessive blood loss or surgical shock, or by the transportation of bacteria from prostate to kidney by the irrigating fluid.

A hemolytic reaction may be recognized at once by measuring the free hemoglobin at the end of the operation. The reaction itself is characterized by chills, nausea, oliguria, a rising urea, mild jaundice, and by an anemia out of proportion to the amount of blood actually lost during or after the operation. The treatment consists in keeping the patient alive until sufficient time has elapsed to permit recovery of the damaged renal epithelium. The hemolytic reaction can be prevented by using an isotonic solution of a poor electrolyte such as 4 per cent glucose solution, as an irrigating medium during transurethral prostatic resection.

CONRAD A. KUTNER, M.D.

Glycine as an Irrigating Solution in Transurethral Resection ERNEST M. NISBET and STANLEY L. GLICKMAN *J Urol*, Balt., 94:5, 59

Creedy believes that the anemia, marked oliguria or anuria, loss of appetite, progressive nitrogen retention and jaundice following transurethral prostatic resection is due to intravascular hemolysis. McLaughlin suggests that the syndrome is produced by the water used as an irrigating medium, which passes into the prostatic plexus of the veins during transurethral resection. Creedy noticed spurts of red urine coming from the urethral orifices during prostatic resection, and he subsequently found a high level of hemoglobin in the plasma of the patient following operation.

In order to facilitate vision when the resectionist has locked into the periprostatic plexus of the veins, the level of the water reservoir may have to be raised inordinately high, to force fluid into the venous system. Varying amounts of hemolysis might result from this course of events.

Nisbet and Glickman did not observe oliguria following transurethral prostatic resection at the University of Michigan Hospital Ann Arbor during the past 16 years. However, the possibility did exist that some of the postoperative morbidity may have been due to unrecognized minor manifestations of this syndrome. None of the authors' patients manifested clinical signs of intravascular hemolysis when preoperative and postoperative samples of plasma or serum were examined.

Many investigators believe that hemoglobinuria in the presence of an acid urine results in the formation of acid hematin which mechanically blocks the renal tubules. Bing thought that the acidosis is a accompany-

ing the anuria may affect the respiratory enzymes of the tubular cells and account for the impaired renal function. This would provide the reason for alkalization when hemoglobinuria exists. Renal vasoconstriction induced by hemoglobinemia may result in ischemia of the tubular cells and account for their diminished function.

In Ross' opinion the fatal renal damage is probably produced by shocking levels of blood pressure and by severe and prolonged reduction of the blood flow through the kidney, the latter being accentuated by hemoglobinemia.

The reduction of alkaline reserve may be associated with methemoglobin in acid glomerular filtrate which would add to the existing tubular damage.

An isotonic irrigating solution that would eliminate the risks of intravascular hemolysis should have the following properties:

1. It must be either nonelectrolytic, or very weakly buffered, for a highly ionizable substance such as sodium chloride allows dispersion of the high frequency current and thereby inhibits its cutting properties.

2. It must be nontoxic when given locally or when administered intravenously.

3. It must be transparent so as not to interfere with visual acuity during the performance of the operation. It must be understood that any isotonic solution used as an irrigating fluid will merely suspend the red blood corpuscles and result in a slightly opaque medium rather than the clear medium produced by the use of distilled water in which complete hemolysis occurs.

4. It must be relatively cheap to permit its use in large quantity.

Creedy suggests the use of 4 per cent glucose solution and reported its use in 158 cases. This solution makes the surgeon's gloves sticky and if the operation is performed on a diabetic, careful observation of the blood sugar is required.

The authors used a 1 per cent solution of glycine in 45 cases of transurethral prostatic resection without demonstrable hemolysis. This solution was found to be abundant and cheap and it fulfilled the requirements of an isotonic irrigating solution.

The average fluid volume used in the trial series of cases was 12,000 c.c. of fluid during each operation. Thus, the glycine cost per operation was 75 cents, or if a 1 per cent solution was used (as it was in 30 patients plus 200 additional cases reported in a note at the end of the paper) the cost of the solution was only 38 cents.

A 10 per cent stock solution of glycine can be sterilized by autoclave in gallon bottles and the solution can be mixed with water when it is needed in the operating room. This method of handling the solution is much easier than making up large quantities in the dilution used at operation.

In conclusion the authors advocate the use of from 1 to 2 per cent of the amino acid glycine as an irrigating solution to eliminate the intravascular hemolysis associated with transurethral prostatic resection.

CONRAD A. KUTNER, M.D.

Varicocele. Surgical Technique Advocated by the Author (Varicocele. Técnica quirúrgica que preconizamos) LUIS ARMANDO BAGLIETTO *Dis. medica B. Atr., 1948* 20 379.

Operation for varicocele is justified because the venous stasis exerts an unfavorable effect on the parenchyma of the testis. A diminution of the exogenous and endocrine secretions is the result.

Two conditions require operative correction (1) varicosities of the veins of the spermatic cord and (2) ptosis of the testis with secondary elongation of the scrotum. Although some workers maintain that only a correction of the varicosities is necessary the author of this article is of the opinion that an orchidopexy is also required.

The author prefers to operate under spinal anesthesia, although the general or local type may also be employed. A 5 to 6 cm. long incision is made slightly above Poupart's ligament. The superficial epigastric artery and vein are ligated and severed. A 2 to 6 cm. long incision is made through the aponeurosis of the external oblique muscle.

Fibers of the cremaster muscle are separated care being taken not to injure the spermatic artery. A 2 cm. long segment of the vein is resected. A concomitant hernia should not be overlooked. A small hernia may escape detection before the operation. This technique as compared with an incision through the scrotum preserves the lymphatic circulation and the sympathetic innervation, allows the discovery of hernia, avoids complications inherent to manipulations of venous plexuses (such as thrombosis embolism hematomas, chronic edema) and permits the re-establishment of a sufficient venous reflex.

The spermatic cord is lifted with a finger placed underneath and an orchidopexy is accomplished by suturing both ends of the severed vein parallel to one another. An eversion of the tunica vaginalis is employed only in the presence of hydrocele. The sutured ends of the spermatic vein are attached with interrupted sutures to the fibers of the cremaster muscle.

JOSEPH K. NARAY M.D.

MISCELLANEOUS

Reiter's Syndrome. R. J. G. MORRISON and M. THOMPSON *Lancet* Lond., 1948 1 636.

The triad consisting of arthritis, conjunctivitis, and urethritis first described by Reiter in 1916 and which now bears his name, was found in 9 cases in the British troops in Western Germany and is reported in detail by the authors. A review of the literature revealed various unusual features of the so-called syndrome of Reiter. Not infrequently one or more components of the triad was absent yet the reporters believed that the disease encountered was actually a manifestation of Reiter's syndrome. It was noted that urethritis might be absent in some cases while in others there might coexist renal complications such as terminal hematuria, hydronephrosis, and chronic pyelonephritis. Recurrences were not uncommon.

A review of 9 cases by the authors revealed uniformly negative smears for gonococci except in 2 of the cases. An elevated sedimentation rate was noted as well as a leucocytosis and sterile pyuria. There appeared to be no association to dysentery. Although the etiological agent is unknown the authors believe that the disease is a manifestation of an unknown allergic phenomenon. This conclusion is somewhat substantiated by the clinical symptoms and signs of arthritis, variable rashes and the increased sedimentation rate. An anemia was noted in one case but was unexplainable. In all cases there was involvement of the knee joints while in only a few of the cases were the small joints of the hands involved. While the condition varied considerably in severity from patient to patient and there was no noticeable response to sulfonamides or penicillin some benefit was apparently derived from intravenous protein shock induced with T. A. B.

PETER L. SCARDINO M.D.

The Venereal Granuloma: A Comparative Study of These Diseases in Florida. WILEY W. WILSON *South. M. J., 1948, 41* 412.

The venereal granulomas (granuloma inguinale, lymphogranuloma venereum and also chancroid), occurring in Florida from 1942 to 1947 were studied by the authors. The diagnostic methods employed included (1) blood serologic studies to rule out syphilis (2) dark field examination for *Treponema pallidum* and other spirochetes (3) smears for gonococci, Donovan bodies, fusospirochetes, Ducrey bacilli, yeasts etc. (4) intradermal tests (Frei and Ducrey) and (5) biopsy for Donovan bodies in tissue section since not infrequently it is difficult to demonstrate these bodies in smears because of marked contamination by other organisms. Although limitations are inherent in the methods they play an important role in the differential diagnosis.

Chancroid lesions developed in from 2 to 3 days after sexual exposure. Positive smears were found in 50.6 per cent of 147 patients examined. Intradermal tests performed with commercial Ducrey vaccine were found positive in 80.6 per cent of the cases in which the clinical diagnosis was chancroid. Therapy consisted of oral sulfathiazole 4 gm. daily. The ulcerative, vegetative lesions of granuloma inguinale extended into the inguinal region, the perineum and about the anus. Lesions about the anus occurred frequently in sexual perverts. The lesions were found to occur both superficially and deep having been demonstrated in lesions of the abdominal viscera, lymph nodes and bones of the thorax. The successful demonstration of Donovan bodies adequately substantiates the diagnosis.

Of 51 patients treated complete healing was obtained in 46 (90.2 per cent) by antimonials and surgical excision. The satisfactory response to streptomycin by two failures in the series prompted the authors to advocate the use of streptomycin in preference to other forms of therapy. Twenty two of the 42 patients with lymphogranuloma venereum

had early lesions occurring most frequently as primary vasculospules on the penis without bubo formation. Of the 6 female patients 4 presented ulceration of the vagina with elephantiasis of the vulva. 42 per cent of the patients showed mild to moderate reaction to the intradermal Frei test and 16 per cent of the patients had a biologically false positive Kahn test. After establishing the diagnosis, sulfathiazole was found to be the drug of choice.

PETER L. SCARDINO, M.D.

Cancer Cells in Urine. CARL J. SCHINDLAPF and VICTOR F. MARSHALL. *J. Urol. Balt.* 1943, 50: 399.

The results of a study of 333 patients examined by the Papanicolaou technique are reported after a 6 months period of follow-up. The cases have been arbitrarily divided into three groups: (1) those with clear evidence of genitourinary cancer at the time of examination of the urine (on the grounds of biopsy or overwhelming clinical evidence); (2) those with a strong suspicion of cancer but in which clinical and biopsy evidence was not conclusive; and (3) those in which there was no suspicion of genitourinary cancer. Dr. Papanicolaou's reports were also reduced to three classes: positive, suspicious, and negative.

In 193 cases there was no evidence of malignant cells in the urine sediment. Of these 16 or 83.8 per cent were clinically noncancerous, 8 or 4.1 per cent were clinically suspicious, and 14 or 7.1 per cent were clinically cancerous.

Fifty-three cases were suspicious according to laboratory reports, but evidence in the smear did not warrant a diagnosis of malignant neoplasia. Of these 24 or 45.3 per cent are clinically cancerous, 6 are suspicious, and 23 were clinically noncancerous.

Eighty-two cases were reported as having definite malignant cells in the smear. Of these 71 or 86.5 per cent were clinically cancerous, 8 were clinically suspicious, and 3 had no evidence of cancer clinically.

The authors caution against the clinical application of this method of diagnosis until a fairly large series has been tested against the usual data, especially biopsy.

JOSEPH E. MARSH, M.D.

Exfoliated Cell of Cancer of the Genitourinary Tract. FREDERICK CHUTE and DAVID W. WILLIAMS. *J. Urol. Balt.* 1943, 50: 604.

The microscopic examination of slides of urinary sediment in the search for exfoliated tumor cells requires much experience, especially as the criteria are not always definite and absolute. The tumor cells are identified largely on the basis of marked variation in size and shape, dark hyperchromatic staining nuclei, giant nuclei, and absolute or relative increase in the size of the nuclei in ratio to the amount of cytoplasm.

The authors have selected 163 cases in which a definite clinical diagnosis was made. 100 of these patients had no malignant disease. Of these 100, 96 (or 96 per cent) were correctly called negative while 4 (or 4 per cent) were incorrectly diagnosed as positive. Fifty-nine patients had malignancy of the urinary tract and in 32 of these (55 per cent) the malignant disease was detected by the smear while it was missed in 27 others (45 per cent).

The cases of malignancy were first diagnosed by smear having been previously partly unsuspected. After a more urological search the tumors were located and confirmed by biopsy. The authors stress the use of fresh specimens of urine and of repeated examinations.

JOSEPH F. MARSH, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

Painful Shoulder: Observations on the Role of the Tendon of the Long Head of the Biceps Brachii in Its Causation. HAROLD H. HITCHCOCK and CHARLES O. BECHTOL. *J Bone Surg* 1943, 30-A 183.

Lesions affecting the tendon of the long head of the biceps brachii are among the more frequent causes of pain and disability in the region of the shoulder joint. In order to determine the incidence of supratubercular ridge and variations in the depth of the intertubercular groove, as well as their significance in producing lesions involving the biceps tendon 100 humeri were examined. The supratubercular ridge was found to be markedly developed in 89 per cent of the humeri and moderately developed in 5 per cent. Contrary to what is often superficially thought, it is not the tendon which slides in the groove but the humerus which moves on the fixed tendon during motions at the shoulder.

Dislocation of the tendon complete or incomplete may be differentiated from peritendinitis by the test of Abbott and Saunders. After full abduction of the shoulder the arm which is held in complete lateral rotation is slowly brought down to the side in the plane of the scapula. A palpable or even audible and sometimes painful click is noted as the biceps tendon now forced against the lesser tubercle becomes dislocated from the groove.

With a frozen, painful shoulder failure of the condition to clear up quickly with manipulation and physical therapy together with persistent tenderness over the intertubercular groove very probably means inflammation and adhesions about the biceps tendon. It should not be forgotten that peritendinitis of the long head may be associated with other lesions about the shoulder such as rupture of the tendon of the supraspinatus. In consequence the peritendinitis may be overlooked, with resultant disappointment in the results of therapy. Where recurrent or traumatic dislocation of the biceps is found surgery is indicated. The authors present 3 cases in which their operative findings were discussed.

Adhesions and peritendinitis of the biceps tendon are usually not seen until the tendon has been exposed by incision of the capsule and transverse humeral ligament the tendon may then be visualized beneath the tendon of the pectoralis major. After exposure of the tendon abduction of the arm will demonstrate whether the humerus slides freely along the tendon or whether it is bound by adhesions under the tendon of the pectoralis major. If such adhesions are present the terminal portion of the tendon will buckle with abduction. An S-shaped skin incision over the deltoid-pectoral interval serves to lessen the

tendency to hypertrophied scar which is common when a straight incision is employed. The tendon is roughened and is sutured beneath this osteoperiosteal flap with heavy silk sutures. The transverse humeral ligament is sewed down over the tendon and the osteoperiosteal flap. The portion of the tendon lying above the transverse humeral ligament is resected. The only residual disability is a slight loss in the power of abduction when the arm is in lateral rotation.

The authors indicate that in these cases of biceps peritendinitis in which the patients do not recover properly after conservative treatment, a much more rapid recovery with less economic loss can be offered by fastening the tendon into the groove. The results in 36 such cases were most satisfactory.

C. FRED GÖRINGER, M.D.

Peritendinous Fibrosis of the Dorsum of the Hand. ROBERT E. VAN DEMARK JOHN D. KOUCKY and FREDERICK J. FISCHER. *J Bone Surg.* 1948 30-A 384.

In contrast to the usual traumatic tenosynovitis which responds to treatment, a painful, persistent, peculiarly hard swelling localized over the dorsal metacarpal area and absent in the palm may follow a blow to the back of the hand.

The authors present the cases of a soldier who suffered from recurrent, disabling hard swelling on the dorsum of the hand following a severe initial blow. In each case, operative exploration and examination of pathological specimens revealed evidence of old and recent hemorrhage with fibrous-tissue proliferation and organization in the hemorrhagic area.

Infiltration of the extensor tendon by the fibrous tissue offers an explanation for the clinical finding of local pain and limitation of movement during flexion of the fingers. It is evident that with extremes of motion, further hemorrhage clotting fibroblastic organization and increased fibrosis occur deep to the superficial fascia. This explains the recurrent, localized and hard character of the swelling.

In such cases it would appear that the treatment of choice is early operative evacuation of the primary hematoma, and ligation of any bleeding vessels followed by a firm compression dressing. Involve organization of the extensor tendons during the fibroblastic wise be avoided with certainty. In late cases evacuation of the hematoma should be followed by prolonged immobilization in order to allow maturation of the fibrous tissue and obliteration of the hematoma cavity.

It has become generally recognized that recurrence of swelling is common. The number of permanently cured cases is reported by Bettman as small. Iselin states that the edema persists indefinitely the

incapacity is often 60 to 75 per cent and the prognosis is very poor. A practical form of treatment is suggested by Watson Jones, who recommends prolonged immobilization in a dorsal plaster splint. This should be continued for several months after the swelling has subsided. C. FRED GÖRINGER, M.D.

FRACTURES AND DISLOCATIONS

The Results of Treatment of Congenital Dislocation of the Hip in Infancy. FREDERICK C. HOLT, M.D. II CITY ED IN R. SCHOTTSTADT AND LOREN J. LARSEN. *J Bone Surg* 1945, 30-A: 454.

The standards of Severin and Ponseti were used in an evaluation of the anatomical and functional results of treatment in 113 cases of dysplasia and dislocation of the hip. The following method of treatment were used:

The abduction frame was used in 32 cases, traction on the Coonse modification of a Pott's frame followed by manipulation was used in 13 cases, manipulation alone was used in 31 cases, remanipulation was used in 8 cases, multiple manipulations (more than three) in 3 cases, open reduction without shell operation was performed in 21 cases, the shell operation only in 2 cases, and no treatment was given in 2 cases. The abduction bar proved very effective in infants under the age of 1½ years. No failures were encountered in effecting satisfactory reduction of the dislocated hip.

Excellent or nearly excellent anatomical results were obtained in 55.4 per cent and excellent functional results were obtained in 60.7 per cent of infants. Deterioration with age was not expected in this group. The best results were obtained with the least traumatic methods, such as the abduction frame and gentle manipulation preceded by traction. The gentler methods of reduction could be used in the youngest age group.

Treatment in infancy produced good anatomical results in 81.3 per cent of cases, and good functional results in 80.4 per cent. All of the patients in this group were less than 14 years of age when the last films were made.

The development of the acetabulum progressed slowly which indicated a probable need for longer periods of fixation after reduction of the hip. Delay in the reduction of dislocations caused increasing maldevelopment of the hip due, in part, to the thickening of the acetabular floor coincident with an increase in the Y co-ordinate.

Aseptic necrosis was observed in 53 per cent of the hips. It was present in only 12 per cent of hips treated by abduction but the incidence following traction and manipulation was 55 per cent and with manipulation alone 74 per cent.

An acetabular angle of 27½ degrees was selected as the upper limit of the normal acetabular index in infancy. In all but 2 patients treated within the first year of life the acetabular index dropped to within normal limits within a period of 18 months. In those patients treated during the second and

third years the descent of the acetabular index appeared more gradual than during the first year and in nearly one half of the patients never dropped as low as 27½ degrees. Only 6 patients in this group actually reached the acetabular index of the normal undislocated hip. VERNON C. TRAXER, M.D.

Results of Treatment of Irreducible Congenital Dislocation of the Hip by Arthrodesis. CHARLES J. FAY. *J Bone Surg* 1945, 30-A: 411.

The author studied the cases of irreducible unilateral congenital dislocation of the hip treated at the Shriners Hospital in St. Louis and at the University of Virginia Hospital and came to the conclusion that as compared with the results obtained by the shell operation or by subtrochanteric osteotomy, arthrodesis offered the most consistently good end result from the standpoint of freedom from pain and satisfactory function. He felt that arthrodesis was especially to be recommended when the economic background was such that the patient would need to do heavy work for a living.

Fourteen patients were treated by arthrodesis, but only 8 had a adequate follow up study. The youngest child was 7 years of age, the oldest 15. Sixteen patients were girls.

In each case an effort was made to reduce the hip by the traction with from 30 to 70 pounds on the affected limb for from 3 to 8 weeks. Counter traction was obtained by extremely high elevation of the foot of the bed. When reduction was not obtained by this method arthrodesis was done in a good position as could be obtained. Prior to traction no surgery shortening averaged 3.2 inches, after arthrodesis shortening averaged 7.5 inches. In no case was there failure to fuse.

VERNON C. TRAXER, M.D.

The End Results of Early Treatment of Congenital Dislocation of the Hip, with an Inquiry into the Factors that Determine the Results. A. B. GILL. *J Bone Surg* 1945, 30-A: 442.

One hundred and five patients were selected for study. Of these, 53 were treated by bloodless reduction only, without subsequent operation. The perfect end-results are to be found only among those cases that are amenable to bloodless reduction.

If open operation is necessary for reduction, one can always observe the presence of one or more of those structural deformities that make the development of a perfect hip impossible. Of marked importance and frequency among these are the deformities of the neck of the femur (anteversion and shortening) and a high attachment of the capsule. Persistent aplasia of the acetabular roof is the most easily remedied of the anatomical defects. Aplasia of the femoral head erroneously called Legg Perthes disease can be observed in practically all cases. Gill believes that this defect is not due to trauma at the time of reduction. Inequality of the size of the acetabulum and head and capsular constrictions also prevent normal development of the hip. In about

6 per cent of the cases, such marked anatomical changes have taken place (absence of proximal femur etc.) that reduction is impossible.

In none of the 33 cases in which hips were operated on before 4 years of age because they were irreducible by manipulation, was a perfect end-result recorded. The author does not deny, but on the contrary strongly affirms that satisfactory and even perfect functional results may be obtained by operative procedures for the correction of the various deformities of the hip but even those with perfect function show some degree of anatomical imperfection.

Approximately 35 per cent of dislocated hips may be expected to become perfect or excellent after bloodless reduction if the reduction is accomplished before the age of 3 years. After 3 years there is a marked decrease in the percentage of successful reductions. However whether the reduction was done in infancy or in the third year seemed to make no difference in the statistics. The author believes that the end result depends upon the degree and importance of the anatomical changes about the hip and that these are not necessarily correlated with the age of the patient. However the normal relationship of the femoral head to the acetabulum may play an important part in the stimulation of the acetabular roof and other parts to normal growth. The congenital dysplasia is caused by a retardation or by an interruption or distortion of the normal growth process. From 15 to 30 per cent of hips may be expected to become functionally 'satisfactory' for a varying number of years, with the understanding that arthritic changes within the hip producing symptoms of fatigue pain and limp are prone to occur sooner or later.

VERNON C. TORNER, M.D.

Follow Up Study of the Early Treatment of Congenital Dislocation of the Hip. C. H. CROGO JR., and J. R. SCHWARTZMAN. *J Bone Surg* 1948 30-A 438.

This article is an analysis of the results of treatment of primary posterior dislocation and primary upward luxation, or subluxation, which occurred in 78 hips in 52 patients. The minimum follow up time was 1 year the maximum 15 years. In approximately 50 per cent of the total number of hips the follow-up study had been continued for 6 years or more. In 71 of the 78 hips dislocation was complete.

Skeletal or skin traction was used to bring the head of the femur into position opposite the acetabulum in all 71 cases. Although the position was obtained within 2 weeks traction was maintained for 4 weeks. Following this and usually with the use of an anesthetic, the head of the femur could be placed easily into the acetabulum by internal rotation and abduction of the thigh. This position was maintained by plaster for 3 months before further treatment was carried out. In no case were the authors unable to bring the head opposite the acetabulum by traction.

Anterior torsion of the femoral neck was found in 71 cases and since experience has shown that the

torsion does not correct itself 'supracondylar rotation osteotomy was done in 67 femurs. In 5 cases it was repeated because of incomplete correction of torsion by the first osteotomy. After 3 months of fixation in plaster following reduction a threaded wire was passed through the bone just above the osteotomy site then the knee and leg were rotated externally to neutral position without fear of disturbing the position of the hip. Further fixation in this position was maintained for 2 months to permit healing of the osteotomy.

In 35 cases open reduction was done when stable seating of the femoral head within the acetabulum could not be accomplished by manipulation. Operation was done to clear away the obstructing fold of capsule and the fatty tissue filling the acetabulum. In many instances the capsule and fatty tissue were eroded by pressure of the head so that after 3 months it became well seated without operation.

If fluoroscopic examination revealed that instability of reduction was due to a shallow socket an acetabular reconstruction was done. This consisted of levering the superior acetabular rim down over the femoral head and backing up the levered rim with cancellous bone chips from the ilium. This was done as an extra-articular procedure. A total of 40 such operations were performed, 3 being repeat procedures. Eight of 10 hips classified as presenting primary upward luxation required acetabular reconstruction. It is stated that the operation may be done satisfactorily at an early age (initial treatment).

The authors condemn forcible manipulation and prolonged fixation in plaster in the frog position. In none of the cases did aseptic necrosis of the femoral head comparable to the changes seen in Perthes disease develop. The authors were able to classify 26 hips (33 per cent) of the 78 as anatomically and functionally normal in this study 22 (28 per cent) were classified as nearly normal 24 (31 per cent) as satisfactory and 6 (8 per cent) as presenting failures.

VERNON C. TORNER, M.D.

Fractures of the Lower End of the Humerus in Children. D. P. McDONNELL and JOHN C. WILSON. *J Bone Surg* 1948 30-A 347.

A series of 176 fractures of the lower end of the humerus in children was reviewed and 88 of these were followed long enough to draw some general conclusions with regard to treatment and complications. Of this latter group 55 were in boys and 33 were in girls. The ages of the patients ranged from 1 to 12 years the average age was 7. There were 53 supracondylar fractures 33 lateral condylar fractures 1 medial epicondylar fracture and 1 epiphyseal separation of the capitellum. A study of the end results in these fractures resulted in the following general conclusions.

Contrary to prevailing opinion, supracondylar fractures can produce serious growth disturbances if the fracture lines extend into the epiphyseal centers. Cubitus varus and cubitus valgus are not considered serious disabilities if flexion and extension are com-

plete. However if the deformity is progressive and is caused by disturbances in the growth centers, disabilities and limitation of motion may occur years after the initial injury.

A satisfactory reduction is one in which the alignment in both planes is good. An anterior or posterior displacement of the fragments, in which the articular surfaces are displaced to a corresponding degree will produce permanent limitations of flexion and extension. Lateral displacement above the epiphysis will produce valgus and various deformities but a good functional elbow may still result.

Supracondylar fractures in which the fracture line or part of it extends into the epiphyses may produce growth disturbances similar to those which result from fractures of the lateral and medial condyles. If the fragment is intra-articular and not attached to overlying bone and soft tissue it will undergo avascular necrosis. Supracondylar fractures of this type should have an accurate anatomical reduction and if the fragments are displaced and rotated an open reduction is probably the best method of obtaining accurate alignment.

A series of lateral condylar fractures in which there were poor results in 50 per cent of the patients treated by closed reduction speaks for the inefficiency of this method. Early open reduction with minimal trauma to soft tissues will give the best results. Avascular necrosis of the capitellum will occur if the fracture line separates the epiphysis from the overlying bone and soft tissues. Fractures of half of the capitellum occurred in a patient with lateral condylar fractures. One had poor apposition by open reduction, and a vascular necrosis occurred in 1 year. In the other the separation was not complete the position was good and healing was uneventful.

Avascular necrosis of the trochlea may occur later despite good reduction of a supracondylar fracture. It can cause stiffness at the joint because of thinning of the cartilage and distortion of the articular surface of the humerus.

Delayed ulnar palsy may cause progressive growth disturbances, and was present in 3 cases of severe cubitus valgus deformity.

Fracture of the medial epicondyle will not cause a serious disability unless the fragment enters the joint cavity. Nonunion is difficult to avoid in closed reduction.

RODOLPH S. REICH, M.D.

Early Operative Treatment of Fractures of the Tarsal Scaphoid (Le traitement opératoire précoce des fractures du scaphoïde tarsien) J. FOULEUX and M. BONVALLET. *Rev. orthop.* Par 1943 34: 58.

These fractures may be classified schematically into the following types: (1) the type of fracture most frequently observed is transverse horizontal or slightly oblique downward and outward separating two fragments of variable size, the upper fragment is generally the largest and is luxated dorsally while the small lower fragment remains attached to the plantar ligaments. (2) the vertical

sagittal type; (3) multiple fractures with crushing of the bone and flattening in the anteroposterior direction. (4) without displacement.

The therapeutic indications vary with the type of fracture as illustrated by cases taken from the literature and a unpublished cases of the authors.

The outstanding fact revealed by study of the different cases is the frequency of unfavorable results following orthopedic treatment of these fractures. There are two main causes for poor results. The first of these is a disturbance in the statics of the foot produced by deformity of the scaphoid which normally constitutes the keystone of the internal arch. This deformity is due to lack of reduction of the original displacement by fracture, secondary reproduction of the displacement or the formation of pseudarthrosis after correct reduction and retention. Particular attention is called to the frequent occurrence of pseudarthrosis which explains the appearance of secondary deformities at the time walking is resumed despite roentgen evidence of satisfactory reduction. The second cause of poor results is astragaloscaphoid and cuneoscaphoid arthritis due to changes in the articular surfaces and tearing of the ligaments. It does not always appear with resumption of walking but several weeks, and sometimes months later. Therefore results declared as good after removal of the cast in orthopedic reduction should not be accepted as valid. These factors are important in fractures with luxation and crushing.

In fractures without displacement and in sagittal fractures which have been correctly reduced immobilization must be maintained for at least 3 months even then pseudarthrosis or arthritis may develop and require secondary arthrodesis. In old fractures arthrodesis after scaphoidectomy is indicated. In fractures with dorsal luxation and in crushing fractures which constitute the most important group the usual concept of treatment must be modified. The frequency of incoercibility of the fracture and of secondary reproduction of the displacement the possibility of the occurrence of arthritis or pseudarthrosis despite correct reduction and immobilization justify consideration of immediate arthrodesis as the treatment of choice. This will save the patient suffering and repeated interventions. The authors favor scaphoidectomy with partial resection of the cuboid and mediolateral arthrodesis a procedure which is not more complex than the English method of ankylosing the astragaloscaphoid and cuneoscaphoid joints by a dorsal tibial graft. It avoids taking the graft and has the advantage of removing the scaphoid, which is subject to pseudarthrosis and of solidly blocking the mediolateral joint.

RICHAUD KENNEL, M.D.

Marrow-Nailing of Recent Fractures, Pseudarthrosis and Bone Plastic. ANDRÉS WESTERMARK. *A. n. Surg.* 1943, 27: 577.

In 1944 the author described his first 28 cases of marrow-nailing of fractures, and he now gives a report on 79 additional cases. Up until January 3, 1946

Fig. 1. (Westerborn) a, Cystic giant cell sarcoma of the tibia. b, After resection, bone transplantation and marrow nailing. c, Four months after operation. d, Twenty months after operation.

marrow nailing was used in 100 cases of which 69 had been recent fractures and 24 pseudarthrosis and in 7 cases plastic bone surgery was done.

The nail is inserted under fluoroscopic supervision or repeatedly checked by several roentgenograms. The author has made use of the latter method and found it satisfactory. The best results are obtained in the nailing of femoral fractures. The nail must be wide enough so that it establishes firm contact with the wall of the marrow cavity mainly in order to prevent rotation between the fragments. One can estimate from the size of the marrow cavity in the roentgenogram about what size nail to choose. The conditions are not so favorable in the tibia as they are in the femur because in the former the cavity is narrowest in the middle. Consequently it is easy to obtain firm fixation of fractures situated in about the middle of the tibia but not of those situated more distally or proximally. If full stability is not obtained with one nail it is wise to insert another one. This needs to be done more often in cases of bones with uneven medullary cavities such as the tibia and humerus than of bones with an even canal. The advantages of medullary nailing are (1) a shortened stay in bed (2) simplified after treatment —no extension (3) less pain and other subjective

trouble (4) less risk of stiff joints muscular atrophy and circulatory disorder and (5) shorter hospitalization and earlier acquirement of working capacity. Marrow nailing involves the danger of bone marrow destruction, fat embolism, and osteomyelitis but experience has shown that the damage that the nail causes to the bone marrow is of little or no practical significance. It is recommended that the nail be removed when full consolidation is established. After a few months the nail generally lies fairly loosely in the marrow cavity. Extended osteomyelitis generally does not develop but only restricted osteitis with local sequestration mainly because of the fact that the pus in the marrow cavity is led off along the nail. According to Kuentscher, Bochler, and others there is never any enclosure of pus with rising pressure in the cavity which pus formation is generally considered to be the cause of. Kuentscher says that when ever there is infection one should drain so that the pus is easily removed but the nail should not be removed since the fracture generally heals in spite of the infection.

The author has made use of medullary nailing in 24 cases of pseudarthrosis. The bone healing was satisfactory in all except 3 cases in which inflamma

tion recurred after operation. A report of the results in 18 cases in Kirschner's clinic indicated that bone healing took place in 15 cases within 6 to 8 months after marrow nailing. In order to hasten the bone healing the marrow nailing may be combined with other operations such as bone transplantation either in the form of bone chips according to Levan der or by covering the pseudarthrosis with a larger bone piece. Often marrow nailing alone is sufficient.

In 6 cases of pseudarthrosis of the thigh bone which persisted from 1 1/2 to 3 years in spite of attempts with many different methods, it was not possible to obtain osseous healing. In 2 of the cases persisting fistulas with a slight discharge were present at the time of operation. In one case the fistula healed soon after the operation. In the other there was still slight suppuration at the time the patient was discharged. In order to avoid the risk of reactivation of a latent infection, sulfathiazole was introduced into the operative wound in all of the cases. In 3 of the 6 cases, consolidation had taken place before the patient was discharged. In the other 3 there were indications that osseous healing would take place shortly.

The new method is vastly superior to the old ones for treatment of femoral pseudarthrosis. The post-operative treatment is very simple. After 1 or 2 weeks in bed the patient is allowed to get up. The prolonged stay in bed before the operation produces more or less marked stiffness in the joints as well as muscular atrophy which necessitates intensive physical therapy. The most important condition for osseous healing is absolutely firm fixation of the fragments. C. F. ZO GOETTER, M. D.

ORTHOPEDICS IN GENERAL

The Serious Limitations and Erroneous Indication of Biopsy in the Diagnosis of Tumors of Bone
JAMES I. BRADFORD, FRANK R. SOKAL, M. D.
948, 4 5

The author engages in an interesting and rather convincing discussion concerning the diagnosis of bone tumors particularly as to whether they are benign or malignant. Attempts at classification based on the histological appearance are of academic rather than of practical importance as they tend toward erroneous interpretations. Certain simple lesions, which resolve completely when undisturbed present histological appearances liable to be interpreted as evidence of malignancy, yet this evidence cannot be obtained without biopsy or more extensive surgery. This cannot be done without causing the patient mental and physical pain or without subjecting the patient to the risks of an anesthetic, complications and the possibility of erroneous interpretations.

The simple lesions have characteristic roentgenographic appearances which can be verified by serial roentgenography without causing pain or subjecting the patient to any risks. Fortunately the diagnosis of bone tumors can be checked by clinical observation and serial roentgenography.

Since amputation at the earliest possible moment does not ensure cure of a malignant tumor and since we have no means of telling whether metastasis has occurred, there is little to be gained by precipitate amputation but much to be gained by clinical and roentgenographic study.

The author takes issue with the attitude of the orthopedic surgeons who prefer to think that the diagnosis of bone tumors is in the province of the surgeon who is called upon to explore the tumor in order to get it out for biopsy studies. It is well known that apparently inoperable lesions may resolve completely. Middlebore interference often secures the desired resolution and may prevent complete resection. Roentgenography on the other hand does not inflict pain or risk on the patient. Serial roentgenographic studies of all bone lesions reveal a great deal without causing any pain to the patient. Such studies permit of more accurate diagnosis and a better treatment of the patient.

If the roentgenographic appearance can be elucidated by inflammation of bony tissue or other disorders it would be reasonable to give a course of appropriate medication in any doubtful case and if this failed to produce a favorable response a course of deep x-ray therapy.

Less questions are presented to the reader by the author with appropriate accuracy. One is convincingly impressed with the more conservative trend and the emphasis which is placed on roentgenology rather than surgery or biopsy studies in the evaluation of bone tumor cases.

Only x-ray hematomas, not only in scurvy and osteogenesis imperfecta but also in limbs with neurovascular disturbances and in hemophilia, and even at the site of suspected fractures, have been mistaken on their clinical and histological evidence as sarcoma. No amputation was done when the patients were considered fit enough to stand the operation. Undoubtedly some of these cases have been regarded as cures by amputation. Although roentgenographs taken of the lungs or skeleton (metastases from osteogenic sarcoma often develop in other parts of the skeleton before they are recognizable) the lungs the latter being at a minimal level may fail to reveal any evidence of metastases, this is no proof that they do not exist. The author makes it a rule to regard any lesion as simple in the first instance if there is definite evidence of trauma and the roentgenographic evidence is such as could have been produced by trauma. Bone lesions with a history of recent trauma and roentgenographic evidence of changes which could have been produced by trauma should be treated with medications, as inflammation notwithstanding serial roentgenographic features which may arouse the suspicion of malignancy.

Remarkable response of carcinomatous metastases from some primary lesions in the breast or prostate to stilbestrol within a few weeks furnishes hope that some such hormone will be found to cure sarcoma. C. FRED GOETTER, M. D.

Bone Changes in the Cat in Experimentally Produced Injury to the Peripheral Nerves. MAURICE A. SCHILLER. *J Bone Surg* 1948, 30A, 469

The history of the development of our concept of the causes of post traumatic bone atrophy is described. This article attempts to throw some light on the argument as to whether the bone atrophy is of organic origin or hysterical.

The author has studied by means of roentgenograms, the bones of the extremities of cats, on each of which section of the sciatic nerve had been done 4 cm. below the sciatic notch. Roentgenograms were obtained of the animals 30, 60, 90, 150 or 180 days after the operation. Apparently one set of roentgenograms was obtained of each animal.

In 11 of 18 cases in which the nerve had been sectioned, followed by primary suture and a cast to the extremity ulcers developed and in 5 of these there was x ray evidence of bone atrophy. In only 1 of 11 patients in whom no cast was used but in whom ulcers developed bone atrophy was found. In 27 patients in whom no cast was used and ulcers did not develop there was no evidence of any bone change.

The author concludes that atrophy of bone does not result from denervation of an extremity nor from immobilization of denervated extremities but that it occurs as a result of ulceration overlying the bone and joint.

VERNON C. TURNER, M.D.

Contractures following Experimentally Produced Peripheral Nerve Lesions. IRVING C. SHERMAN. *J Bone Surg* 1948, 30A, 474.

The author reports the following methods by which contractures develop following peripheral nerve injuries.

1. There may be adaptive shortening of an active innervated muscle because of the lack of opposition of the paralyzed antagonist. This is called a myostatic contracture.

2. An active contracture may develop in muscles when the motor nerve is irritated or compressed.

3. Neurogenic protective contractures may follow peripheral neuritis.

4. Sympathetic nervous system disturbance following mild trauma and associated with traumatic vasomotor and thermic changes in the extremity also produce contractures similar to those seen in rheumatoid arthritis.

5. Fascial shrinkage will produce contracture as exemplified by Dupuytren's contracture of the hand.

6. "Set" contractures gradually develop after from 6 to 8 weeks of immobilization combined with denervation of a muscle as in poliomyelitis.

7. Contractures may result after splinting an extremity because of hysteria or habit.

The author studied the contractures of the main muscles of the extremities of cats in which denervation was accomplished by sectioning the sciatic nerve 4 cm. below the sciatic notch. Some of the animals were subjected to primary suture of the nerve others to delayed suture and some to immobilization of

the extremity in casts following denervation. The contractures were measured as to the degree of limitation of motion with and without anesthesia. Finally the animal was sacrificed and the tendons were cut to be sure that the limitation of motion was due to muscle shortening rather than capsular or joint changes.

The author found that contractures developed in 100 per cent of the denervated muscles maintained in a shortened position by casts for from 45 to 105 days. On microscopic examination of the muscle there was found to be excessive fibrous tissue. Contractures developed in 84 per cent of the animals following primary suture and in 100 per cent following delayed suture after 90 days. The contractures were less severe less frequent, and less persistent after primary suture than after delayed suture in untreated animals. The longer the difference in time between the recovery of the opposing muscles, the more likely was the development of contracture in the muscle which recovered first.

If electrotherapy was used there was a delay in the appearance of the contractures but if it was used for a long period the frequency and severity approximated those in the untreated animals. Electrotherapy favors the development of contractures in the unparalyzed antagonists of paralyzed muscles. Electrotherapy is therefore favorable in the early treatment of paralysis but not in the late treatment.

Since the frequency and severity of contractures were greater after delayed than after immediate suture one is justified in urging early operation after severance of a peripheral nerve.

VERNON C. TURNER, M.D.

Congenital Absence of the Humeral Head. A. T. ANDERSEN. *J Bone Surg*, 1948, 30B, 333.

The author reports 2 cases of unrecognized congenital absence of the humeral head. Only 6 cases with a similar roentgenographic appearance could be collected from the literature. Experimental data suggests that the time in development at which the fault occurred was probably the joint stage just when the articular rudiments had separated.

The essential features are complete or incomplete absence of the humeral head with a rudimentary glenoid fossa. The deformity may be unilateral or bilateral. It may be isolated or one of a number of deformities in the same patient. There is relatively slight disability. The humerus is short and abduction movement of the shoulder is limited.

DANIEL H. LEVINTHAL, M.D.

Function of the Cruciate Ligaments of the Knee Joint. A. J. HELPER. *Lancet* Lond. 1948, 1, 665.

The author questions the generally accepted thesis that the cruciate ligaments control the anteroposterior stability of the knee joint. Through anatomical and clinical study he deduces that the cruciate ligaments serve as guide ropes during rotation at the knee joint. Since the medial collateral ligament is fan-shaped and part of the fan is taut in

every position of the knee joint the finding of anteroposterior laxity is probably due in part if not chiefly to the rupture or weakness of this ligament.

The author's observations indicate that the tibia rotates laterally on the femur in the last 30 to 40 degrees of extension; conversely it rotates medially during the last portion of flexion. The anterior cruciate ligament remains at constant tension during extension and the posterior cruciate acts similarly in flexion.

If the tibia is prevented from lateral rotation during extension the anterior cruciate ligament is seen to be stretched tightly over the lateral border of the medial femoral condyle. This may be observed at operation if a dislocated meniscus, or rotation may be prevented manually at operative or laboratory examination. This may be the source of medial femoral condyle erosion noted frequently at operation for a medial meniscus.

In bucket handle tears of the medial meniscus, the lateral rotation of the tibia on knee extension is prevented. Thus at full extension the anterior cruciate ligament must be torn at the time of injury.

gradually stretched during convalescence when full extension is acquired. The fact that lateral rotation is prevented during extension in this type of

meniscus tear serves as a clinical test in diagnosing knee injuries. Although extension may not be complete in effusion or injuries to the fat pad, lateral rotation takes place.

The author notes that anteroposterior laxity of the knee joint in ligamentous injury is almost always associated with tears of the medial collateral and the anterior cruciate ligaments.

With the hypothesis that much of the sensation of weakness and instability of the knee joint with relaxations of the ligaments comes from loss of control of rotation the author suggests certain tendon transplantations to insure lateral rotation of the tibia during extension and medial rotation on flexion.

He advises medial transplantation of the patellar tendon insertion to a distal lateral rotation of the tibia, and transplantation of the course of the semitendinosus tendon into a groove in the medial femoral condyle to facilitate active medial rotation during flexion.

A report of 7 cases of anteroposterior instability of the knee with satisfactory results is given. The patients have fairly good knee control and stability on walking up and down stairs and on rough ground. At rest the abnormal movement is present as prior to operation.

KENNETH H. SPENCER, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Surgery in Peripheral Vascular Disease. HARRIS B STUMACKER. *Surg. Clin. N. America*, 1943, 28, 294.

In the present communication it is the author's purpose to discuss general principles in the treatment of peripheral vascular disease and the application of some of the commonly used surgical measures. He makes no effort to present the detailed management of patients suffering from these disorders nor to consider all the operative procedures of value. The author hopes that this approach will not convey the impression that he holds lightly the importance of the most minute attention to details in prevention, diagnosis and treatment of the peripheral vascular disorders.

It must be recognized that certain limitations exist in the prevention and treatment of peripheral vascular diseases and injuries. In the first place at the present time very little or nothing concerning the precise etiology of most of these disorders is known therefore prevention is impossible. Another limitation which must be recognized is the fact that, in general, the vascular disorders are associated with irreparable changes. A third limitation in treatment concerns the common delay in seeking medical advice. Many of the chronic vascular disorders have an insidious onset and as a general rule patients fail to appreciate the significance of the initial complaints. These limitations just mentioned pertain to the disease processes and to the individuals who suffer from them. There are also unfortunately, certain limitations which arise as a direct failing of the medical profession. The first concerns a too widespread lack of understanding of the method of obtaining a vascular history and of performing a vascular examination, and a corresponding lack of diagnostic training in medical schools and in postgraduate education. An occasional related failing of the medical profession concerns a lack of appreciation of the gravity of the situation imposed by significant reduction in blood supply.

The author discusses some of the common surgical operations which are applicable. Sympathectomy, crushing of sensory nerves, amputation plastic procedures and arterial embolectomy are discussed. In summary the fundamental principles underlying the treatment of peripheral vascular disorders have been discussed and the basis for certain of the commonly applied operative procedures has been presented. It is believed that surgery has much to offer in the treatment of these harassing difficulties provided that the limitations are recognized that the procedures are utilized upon reasonable indications and are both skillfully performed and supplemented by proved nonoperative aids.

HERBERT F. THURSTON, M.D.

Portacaval Anastomosis—Observations on Technique and Postoperative Care. ARTHUR H. BLAKEMORE. *Surg. Clin. N. America* 1948 23 279

The author notes that clinicians familiar with the natural history of Laennec's cirrhosis of the liver are well aware of the role of portal hypertension in that disease. In an analysis of 386 cases of portal cirrhosis of the liver Ratnoff and Patek noted rupture of esophageal varices as the cause of death in 26 per cent of the cases.

Cirrhosis of the liver secondary to hepatitis is a not uncommon cause of portal hypertension and bleeding from esophageal varices. Banti's syndrome with esophageal varices secondary to portal hypertension invariably leads to death, sooner or later from hemorrhage. Schistosomiasis of the liver that has developed to the point of causing esophageal varices as the result of portal obstruction almost invariably causes death eventually from hematemesis. Finally in 3 cases of the present series, repeated hematemesis resulted from portal vein obstruction secondary to pancreatitis. The above conditions are considered the common causes of portal hypertension.

When one considers that portal hypertension is one common factor that is responsible for dire consequences it is not surprising that the subject has received considerable thought in the past. In fact, ever since Von Eck in 1877 anastomosed the portal vein to the vena cava in dogs surgeons have accepted the rationale of portacaval shunt for the amelioration of portal hypertension. Though the rationale of the procedure was early accepted many years were required to forge those advances in surgery so essential to its clinical success.

A method of establishing portacaval shunts to be clinically acceptable must meet two important requirements: (1) a high chance of survival for the patient; (2) a high likelihood of maintained patency of the anastomosis.

The author notes that to date portacaval anastomoses have been accomplished forty times with a postoperative mortality of 25 per cent. Success of the portacaval shunt procedure depends primarily upon the selection of cases for operation, careful attention to technical details, and upon preoperative and postoperative handling.

The most serious handicap in the beginning was inadequate knowledge upon which to base an intelligent evaluation of the relative operative risk in a given case. This was particularly true when dealing with cases of cirrhosis of the liver and accounted for 5 of the postoperative deaths.

The onus of infection must always be kept foremost in mind. The subtlety with which a so-called low grade green streptococcus can wreck by thrombosis an otherwise perfect anastomosis should be a caution to all. In the course of a year following the

introduction of the electrothermic method for the treatment of aneurysms at the Presbyterian Hospital New York the following routine was established for the prevention of infection: (1) rigid asepsis on the part of the operating team regarding the wearing of helmets, masks, scrubbing, and otherwise scrupulous individual precautions, (2) skin preparation by a soap and water scrub followed by alcohol ether iodine and alcohol (3) meticulous covering of the skin edge as follows: make the skin incision ligate superficial blood vessels with fine silk, cover the skin edge with towels held in place by closely spaced Michel clips reinforced with a towel slip at either end of the wound, discard all used instruments and change the gloves before proceeding with the operation (4) the prevention of air borne infection by a bacteriologically controlled system of ultraviolet lights (5) a pleasant but not essential addition to the foregoing regimen for the operating room is air conditioning.

Before the institution of this outlined regimen for the prevention of infection a total of 5 patients with a red aneurysm infected all of whom succumbed. After the institution of the combined regimen some 300 wiring operations for aneurysm were performed at the Presbyterian Hospital over a 10 year period without a single infection. Recent experience has shown that penicillin even in large doses cannot be depended upon to prevent infection in cases of aneurysm undergoing the wiring operation. In 3 cases in which penicillin was given in 100,000 unit doses before wiring and for 14 days after operation at 3 hour intervals infection developed in the aneurysm in each case. A *Streptococcus viridians* organism was recovered from both. The only other variation of routine in these operations was the omission of ultraviolet radiation. The above distiction is made not to discourage the use of penicillin but to illustrate that there are bacteria resistant to its action and the failure to use ultraviolet radiation in these 3 cases has the appearance of a serious omission which shall not be repeated in the future.

In regard to the suture versus nonsuture method, the author notes that there is not yet conclusive proof that the suture method is superior. The score in 3 proved cases is nonsuture anastomosis closed 3 cases suture anastomosis closed 1 case. All were splenorenal anastomoses. The nonsuture method however does have the advantage of conserving the kidney in the splenorenal type of portacaval shunt.

The author discusses factors which stem basically from the hemodynamics of the venous system which in general when compared to the arterial system, are unfavorable for the continued patency of anastomoses. According to the author the following measures should be taken in portacaval anastomosis: (1) the avoidance of twisting of the anastomosed veins or angulation upon repositioning of the viscera (2) measures to maintain the blood pressure at satisfactory levels from the time the anastomosis is opened until it is healed (3) measures to prevent

abdominal distention (4) avoidance of early ambulation and (5) anticoagulant therapy. The accuracy of blood clotting time determinations is, of course the first prerequisite to safe heparinization in these cases.

A great deal of unnecessary confusion and blood loss may be eliminated at the time of opening the anastomosis if the surgeon has properly and carefully ligated with transfusion ligatures all venous branches in mobilizing the splenic vein before starting the anastomosis. Usually a 4 cm. to 5 cm. segment of splenic vein is adequate. Extreme care must be taken in accurate placement of the first anastomosis sutures to prevent twisting of the splenic vein. Any significant angulation of the splenic vein should disappear upon replacement of the kidney in its normal position posteriorly. In summary the author has reviewed some of the common causes of portal hypertension. The rationale of the portacaval shunt for the control of gastrointestinal hemorrhage due to portal hypertension is discussed. Factors having a bearing upon the operative risk and success of the portacaval shunt procedure are emphasized. Points in technique are discussed.

HENRY T F THORNTON, M.D.

Arterial Anastomosis in War Wounds of the Extremities. WILLIAM F MACFEE, Surg. Col. F. America, 628 23 351

War wounds involving the peripheral arteries are among the most distressing encountered, for they may appear to be limited in extent and yet become disastrous in consequence. The total incidence of arterial injuries in the armed forces of the United States in World War II was 0.6 per cent, and in wounds of the extremities 1.4 per cent. Usually the casualty has multiple wounds and there is widespread destruction of soft tissue which precludes simple suture repair of the vessel.

Rose, Hess, and Welch demonstrated that the arteries of greatest surgical importance in war wounds are the axillary, brachial, femoral, and popliteal. The principal injuries found in these arteries are spasm, contusion, complete and incomplete lacerations, traumatic aneurysms, and arteriovenous fistula. The definitive treatment of the last two is delayed weeks to months and need not concern the forward hospital.

Sympathetic block with procaine was the procedure most often used for arterial spasm. Results were sometimes good but not consistently so, and it is probable that the method could not be given a fair trial under combat conditions. Arterial constriction results in thrombosis if the intima is broken, and in late secondary hemorrhage with hematoma formation and its complications if the arterial wall is sufficiently damaged. Embolectomy is less helpful than might be thought for the procedure is useless without anticoagulants, and these agents are almost impossible to use in the forward area. The immediate danger from incomplete laceration is fatal hemorrhage. It is the wound which if seen

early, is most favorable for simple suture repair. If seen late when thrombosis has occurred in the distal arterial tree a satisfactory outcome may be hoped for. Completely severed arteries can be treated adequately in most cases only by some method of bridging the gap for there is wide retraction of the cut ends, destruction of collateral vessels, and loss of soft tissues with a segment of the major vessel. Blakemore and his associates using a vein graft with vitallium tubes or cuffs believed that a basis for success for this type of anastomosis was established for the first time, for infection and thrombosis could be controlled with anticoagulants sulfonamides and penicillin. The total reported experience of several authors is thought to be insufficient to warrant a clear appraisal of its worth yet it seems to be a step in the right direction. Glass and plastic (alkathene) tubes with and without vein grafts were also utilized for this type of injury.

Tables are given of the results reported by several authors, of these various methods of restoration of the injured vessel. A comparison is also furnished of the end results obtained by all methods of treatment without regard for the author. These results need not be reported in detail, for the wide discrepancies between the results obtained by different authors make interpretation extremely difficult, and indicate the many variables present in a problem of this nature.

It is obvious that a satisfactory method of restoring the function of an artery severed by a high velocity missile is yet to be developed. The prepared vein graft of Blakemore the use of anticoagulant although generally unsatisfactory in the field and the antibiotic preparations are partial answers to the problem. It may be that the inevitable conditions of warfare may be more responsible for the failures than the methods employed.

ALLAN D. CULLOW, M.D.

Fourteen Attempts at Arterial Thrombectomy Following the Method of Jean Cld dos Santos.
Doobstruent Thromboendarteriectomie (Quatre cas de thromboectomie artérielle suivant la méthode de Jean Cld dos Santos. Thrombo-endarteriectomie doobstruante). *Rev. Leriche.*
Mém. Acad. chir., Par. 1948, 74 100

The author describes his experience in 14 attempts at thrombectomy for arterial thrombosis. With the technique described by dos Santos a line of cleavage is established between the media and inner elastic lamina so that the arterial intima is removed with the thrombus. At times a good part of the media is also removed with the clot. When the arterial lumen has been cleared the blood flow is restored through a tube in which there is no endothelium. Heparin is administered routinely but even when the period of heparinization was limited (by hemorrhage) to 45 hours there was no clotting.

The operation requires exposure of the full length of the thrombosed artery in order that hemostatic forceps may be placed above and below the throm-

bus as well as on all the patent branches. Originally following dos Santos the author and his assistant attempted to ream out the thrombus and the adherent endothelium with a bistoury starting from either end. They now use the technique of Reboil in which the artery is incised its full length. After the thrombectomy has been completed the artery is reconstructed with a continuous lock stitch of fine silk. Before the clamps are released the artery is filled with serum in order to detect leaks and drive out the air. Heparin is injected into the artery at the end of the operative period. In 3 cases severe hemorrhage was attributed to heparin it was fatal in 1 of them.

In the 14 attempts 7 operations were completed as planned. One patient died of hemorrhage with a permeable artery. Three patients had excellent results and 2 had recurrence of the thrombosis. The author does not give the result in the seventh case.

Because of the uncertainty of the operation it is suggested that lumbar sympathectomy should also be performed but at an earlier time because of the danger of hemorrhage when heparin is used to safeguard the patency of the thrombectomized artery.

THEODORE B. MAXWELL, M.D.

So-called Syndrome of Arterial Embolism and Acute Ischemia of the Extremities (Syndrome d'embolie artérielle et ischémie aiguë des membres). MARC JERLEY and HENRI DE BALBAZ. *Mém. Acad. chir., Par., 1948 74 337*

The authors show that the classical concepts regarding aseptic embolism of the extremities do not explain all the facts found and published by many surgeons but a study of 9 personal cases has allowed them to elaborate a totally different theory. These 9 cases presented a nearly identical symptomatology but differed greatly in operative and autopsy findings. This puzzled the authors until they decided to abandon the embolic hypothesis and to accept arrest of the arterial pulsations as the initial primary phenomenon, and the formation of clots as a second condition of the patient. This postulate explained everything.

Because a clot was found in the artery in some cases after an ischemic syndrome the classical concept concluded that the clot arrived there by migration although this could not be proved in the majority of cases. However, it is more in accord with clinical observation and more fruitful in therapeutic conclusions to separate the known facts from guesses at the mode of appearance. The incontrovertible facts are the following: (1) a characteristic clinical syndrome consisting of severe pain, stupor of the extremity signs of gangrene progressing rapidly and absence of pulsations and oscillations and (2) variable anatomic or operative findings: the artery may be obstructed or free its walls altered or intact, and the neighboring veins normal or thrombosed, and the it is appropriate to describe simply an anatomoclinical syndrome of acute ischemia of the extremities of

variable etiology including arteritis (pseudembolic form of chronic arteritis), spasm, embolism, phlebitis and even traumatism. Whatever the origin may be the course to follow is the same.

Medical treatment: emergency administration of heparin and then of dicumarol; the latter under laboratory control. At the same time treatment of the spasm with papaverine given intravenously and slowly (from 0.06 to 0.20 gm. in the first 2 hours) and by novocain infiltration of the sympathetic. A period of 24 hours seems to be long enough to determine whether the treatment will succeed or fail.

Operative indications if the patient is in an alarming condition with circulatory failure operation is useless. If he is in good condition the lesion being only local, the decision to operate must be based exclusively on the persistence of pain and the sign of clinical ischemia.

Choice of operative method after exposure of the artery under local anesthesia, the following conditions may be encountered and the intervention will vary accordingly: (a) Venous thrombosis separate from the artery from the vein and, if the arterial pulsations return phlebectomy only. (b) Hard and thrombosed artery with periarthritis arteriectomy by the collateral route. (c) Small spasmotic, hard and probably thrombosed artery arteriotomy to remove the clot. If blood continues to dribble rolling of the artery as high as possible. If this is unsuccessful introduction of an oiled sound to verify the absence of an obstacle. (d) Doubtful case. Leriche resect the artery when the endothelium seen through the arteriotomy wound is altered. When speed is indicated by the patient's condition when suture is made difficult by the local conditions, when the thrombus recurs immediately after suture and when there is an embolism from an infected endocarditis.

Periarterial sympathectomy should be added if it will not complicate the intervention. It is advisable to inject heparin directly into the artery before closing it. In general if the pulsations return the prognosis is good. If they do not the prognosis is poor and all possible measures must be utilized.

Of the 9 patients operated upon 4 survived and 5 died.

BLOOD TRANSFUSION

The Influence of Electric Shock and Adrenaline Injection on Leucopoiesis and Erythropoiesis.
H. M. MORTLAND. *Brit med J* 1917 129 Supp. 30.

The purpose of this investigation was (1) to find out whether severe stimulation of the central nervous system by electric shock influences hematopoiesis, and (2) to study the effect of adrenaline injection on leucopoiesis and erythropoiesis.

There were no consistent effects of electric shock on the blood picture, but the bone marrow revealed a slight increase in the ratio of myeloblasts, promyelocytes and myelocytes to granulocyte forms. After adrenaline injection the increase in mature granulocytes and lymphocytes seemed to originate in the blood-forming organs.

These observations do not prove the existence of a neurogenic regulation of hematopoiesis, but the author believes that "they give a certain technical support to the assumption that it already occurs in physiological conditions."

There is a complete discussion of the literature on this subject with a bibliography of more than 400 references. The monograph should be of considerable interest to investigators in this field.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Amiotomic Amputations (Amputações amiotómicas)
F. PAES DE VASCONCELOS. *Arg. Med.* 1947 19 66.

Because there is no satisfactory technique of amputation for the root of the extremities in serious cases the author proposes a new method which (1) causes little shock (2) eliminates all elements which may maintain or favor the progress of the morbid factor (3) assures good exposure of the infected parts when the amputation stump must remain open, avoids secondary contamination of the noninfected parts and allows easy secondary suture of the wound (4) assures the functional value of the stump, and (5) facilitates a higher type of amputation by extending the incisions, thus complying with the therapeutic indications found during operation.

To fulfill these requirements the author obeys the following rules. He does not section the muscular mass the muscle is completely extirpated or is left entirely in the stump in accordance with the amiotomic rule. He makes the cutaneous incisions so as to outline two flaps which come together over the sites of the vessels and of the muscles which are more deeply inserted. Thus, prolongation of the incisions allows a higher type of amputation improves drainage and exposure and above all facilitates the maneuver of detaching the insertion of muscles. On the other hand, the cutaneous flaps form two valves one contains the muscle which was entirely left behind, is attached to the flap by aponeurotic expansions and will cover the bone stump with its tendinous portion thus avoiding exposure of the bone stump and insuring easy secondary suture when the amputation stump must remain open the other valve covers a large and amply exposed space corresponding to the vessels and the removed muscles through which infection could spread more easily and dangerously.

The author refers to the general principles of the technique and classifies the cases in which it is indicated. He describes in detail the technique of amputation for the root of the upper extremity which he calls subdeltoid amiotomic amputation, and for the root of the lower extremity which he calls 'infratrochanteric amiotomic amputation'. He reports his cases and shows how to perform atypical amputations in accordance with the amiotomic technique.

RICHARD KEEHL, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Ulceroglandular Tularemia Treated with Streptomycin. RAYMOND E. LESSER and SOWMY MILLER.
N. England J. M., 1948 238 554.

The authors report 2 cases of ulceroglandular tularemia in which they noted the efficacy of strepto-

mycin therapy in the chronic phase of the disease. The effectiveness of streptomycin treatment in these cases parallels that which has appeared in the literature to date. The second case was of particular interest since it illustrated the clinical course of a 26 year old paratrooper who was hospitalized some 3 months after the origin of the disease.

During the hospital stay the patient was afebrile. With the establishment of the diagnosis of tularemia, streptomycin therapy consisting of 0.2 gm every 4 hours for a total of 4.4 gm over a 4-day period was instituted. During treatment there was beginning regression of the lymphadenopathy and diminution of the weakness. One week later all tenderness of the lymph nodes had subsided but slight residual adenopathy remained. After discharge the man was seen periodically as an outpatient. Objective and subjective improvement continued with complete resolution of the adenopathy and with ability to carry on with military performances. Except for weakness and nausea following exertion the patient remained well until about 9 months after the streptomycin therapy when he experienced a mild aching sensation in the left thigh left leg and left lower quadrant.

Some 11 months after his first hospital admission the patient was readmitted to the hospital. Because of the rise in the agglutination titer as well as the significant change in clinical course it was believed that he was experiencing a relapse. Therefore streptomycin was started consisting of 3 gm daily for 7 days in divided doses or a total of 21 gm. At the conclusion of therapy the patient felt markedly improved, and the adenopathy slowly regressed. Previously, he had lost 15 pounds in weight. One month after therapy he had regained 7 pounds.

Although the clinical response to streptomycin was definite the subsequent course of the disease indicates probable inadequacy of dosage initially. It may also indicate decreased effectiveness of treatment when a delay occurs between the initial phase of the disease and the institution of therapy. The inability of streptomycin to effect lasting remission in Case 2 was probably due not only to this fact but also to the development of resistance by the organism to the antibiotic agent. The initial amount of streptomycin used may be considered inadequate in the light of current knowledge of organism sensitivity.

C. FRED GORDON, M.D.

ANESTHESIA

The Use of Prolonged Continuous Spinal Anesthesia to Relieve Vasospasm and Pain in Peripheral Embolism. SCOTT M. SMITH and VINCENT L. RICE. *Anesthesiology* 1948, 9 329.

The value of interrupting the sympathetic impulses to peripheral vessels in cases of embolism has

been well established. In the lower extremities it may be accomplished by the administration of spinal anesthesia. This will provide immediate relief of pain and vasospasm and allow one to evaluate the circulation. Procaine is probably the agent of choice and is perhaps best used in a 1 per cent solution.

Prolonged continuous spinal anesthesia has been used in the management of 3 cases of peripheral embolism. In 3 other patients single injection spinal anesthesia was employed for the relief of pain and vasospasm.

No neurologic changes were noted in any of the cases in which prolonged continuous spinal anesthesia was employed. It was noticed, however that despite the agent used the relative duration and effectiveness of the anesthetic agent became progressively less and in 2 of the 3 cases two agents were used to prolong the anesthesia to 60 hours and 43 minutes and 43 hours respectively. A total of 4.45 mgm. of procaine was used in 1 case over a 44 hour period.

Single injection anesthesia and prolonged continuous spinal anesthesia are valuable aids in the treatment of peripheral embolism. In some instances, surgical removal of the embolus may not be necessary when adequate block of the sympathetic nerves to the involved extremity is maintained. Surgical intervention should not be delayed when there is questionable improvement following the sympathetic block. The use of cooling by any method should be avoided. Delay and procrastination have no place in the treatment of peripheral embolism.

MARY FRANCES FOX, M.D.

Combined Anesthesia for Cesarean Section (Low Transverse) NORA D. DEAN. *Current Res. Anesth.*, 948, 7-80.

This author gives a clinical résumé of combinations of anesthetics used in 66 low transverse, cesarean sections at the Memorial Hospital, Louisville, Kentucky over a year period. The agents used were combined procaine and pontocaine as a spinal anesthetic, with pentothal sodium intravenously. Preoperatively 1/150 gr. of atropine was given subcutaneously. Fifty milligrams of ephedrine in novocain were injected subcutaneously at the site of the spinal puncture. The solution used was 50 mgm. of procaine crystals dissolved in 5 mgm. of a 2 per cent solution of pontocaine. This solution was mixed with the same needle which was used in mixing the ephedrine novocain for infiltration thus sufficient ephedrine was present to cause a delay in the absorption of the combined anesthetic agent. The solution was further diluted up to 1/4 to 3 c.c. with spinal fluid before injection into the subarachnoid space took place then the patient was placed in a supine

position until the surgeon was ready to make the incision. The patient was shifted to a 35 degree Trendelenburg position and a c.c. of 1/4 per cent pentothal were injected intravenously as the incision was made. The amount of pentothal sodium solution given was only sufficient to keep the patient in a degree of sedation comparable to a normal sleep. Oxygen was given to avoid the depression of pentothal.

The presence of dyspnea, especially of cardiac origin, was considered a contraindication to the use of pentothal. In none of the 66 cases reported was resuscitation of the baby necessary. The author presents 3 cases in which the use of the combined anesthetic was indicated. This combination seems to produce adequate anesthesia with a subanesthetic dosage of all drugs used. Side effects and postoperative complications were reduced to a minimum.

MARY KARP, M.D.

Secoral as a Basal Anesthetic for Children. MARY FRANCES FOX and MARY KARP. *Current Res. Anesth.* 948, 27-33.

In an attempt to alleviate the psychic trauma of a child undergoing surgical intervention four groups of patients involving 100 cases were given varying proportions of secoral and atropine, or secoral and demerol. The medication evolved combines the dosage of secoral of approximately .05 gr. per pound plus demerol and atropine sulfate. A total of 3 gr. of secoral was not exceeded for it was the intention to produce sedation only in the older child.

Pontocaine Hydrochloride for Brachial Block Anesthesia: 150 Cases. DANIEL C. MOORE. *Anesthesiology* 948, 9-15.

Brachial block has become a favorite type of anesthesia for operations on the hand. From 5 to 6 hours operating time was obtained with brachial blocks in which 0.1 per cent or 0.15 per cent pontocaine solutions were employed. Anesthesia was established in from 30 to 40 minutes. Sensory loss occurs ten to twenty minutes before muscular movements are abolished. Successful blocks were obtained in 96 per cent of the cases.

Postoperatively there is no need for an opiate until a period of 6 to 8 hours has elapsed. No complications or injuries to the brachial plexus have occurred from the prolonged action of the pontocaine. Up to the present time no untoward effects have occurred during or following the use of pontocaine. Some of the unpleasant effects of procaine and epinephrine have not been noted. When spinal anesthesia is used with brachial block pontocaine is the drug of choice because of its lasting effects.

MARY FRANCES FOX, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Roentgenological Manifestations of Intrathoracic Injury Due to Missiles. WILLIAM A. EVANS, JR.
Am J Roentg., 1948 59 66a

This study is based on observations made in the x ray service of an overseas General Hospital of the United States Army. During a period of 6 months 400 battle casualties were admitted approximately 5 per cent of whom had wounds involving the intrathoracic structures.

Roentgen manifestations of thoracic injuries are usually multiple. The most common findings are (1) foreign bodies in the lung (2) lesions of the pulmonary parenchyma (3) pneumothorax and hemothorax, and (4) lesions and foreign bodies in the mediastinum.

Foreign bodies. Metallic fragments lying in the substance of the lung are seen frequently. In a large proportion of the cases there is no other evidence of injury to the pleura or lung parenchyma and even after prolonged periods no reaction in the adjacent tissues develops. Not infrequently foreign bodies penetrate close to the mediastinum or hilum. The question arises whether in such instances pulsations transmitted to them may not produce a delayed perforation. This hazard must be balanced against the hazard of their operative removal.

Traumatic pneumonia. In several cases an area of infiltration has been observed along the path of the missile suggesting a traumatic origin. The infiltration was rather diffuse in the beginning then it became sharply circumscribed of spherical or ovoid shape and within a few weeks it completely disappeared. Such a lesion most probably represents a hemorrhagic infiltration from rupture of a large blood vessel with subsequent clotting organization and resolution.

Pleural manifestations. The most common and most serious complications due to intrathoracic injury have been hemothorax and pneumothorax usually occurring together. Under favorable circumstances the air and exudate will disappear in 2 or 3 weeks. If resolution has not occurred after this critical period of 2 weeks a greatly prolonged course may be anticipated with irreversible changes as sequelae. The blood in the pleural cavity acts as an irritant provoking an outpouring of serofibrinous exudate from the pleural surfaces. Later there is formation of fibrin clots with thickening of the pleura over a collapsed lung. The amount of pleural exudate may continue to increase despite repeated aspirations. In such instances more radical measures become necessary to evacuate the pleural space. If the lung has been collapsed over a long period thoracoplasty may eventually have to be performed.

An interesting observation was the marked tendency to encapsulation of the pleural contents after

the critical period. The encapsulated pocket or pockets as a rule formed posteriorly due to the recumbent position of the patient.

Rarely interstitial emphysema of the chest wall was noted. It was thought that in case of tension pneumothorax the air escapes through a rent in the parietal pleura, accounting for the interstitial emphysema. A complete collapse of the lung and a marked displacement of the mediastinum are strongly indicative of a tension pneumothorax. When both air and exudate escape from the pleural space cellulitis and abscess formation of the chest wall are likely to result.

Mediastinal involvement. Cases of foreign bodies in the mediastinum have been rare since the large majority of such injuries are rapidly fatal from hemorrhage. In those patients who survived, a decision as to a later surgical removal of the foreign body was most difficult. Cases have been observed in which a late perforation of a large vessel occurred apparently from a slow erosion produced by vascular pulsation. The presence of a large cardiac shadow in patients with missile injuries of the thorax raises the suspicion of a pericardial effusion.

The author gives the brief histories of 14 more or less typical cases in which numerous roentgenograms were used for illustration. T. LEVONIA, M.D.

Roentgen Examination in Acute Dilatation of the Stomach. J. FERMAN DAHL. *Acta radiol. Stockh.* 1948 29 237

The author presents the roentgen findings in 20 cases of acute dilatation of the stomach to demonstrate some of the most characteristic forms of this condition.

The acute gastrectasias may be divided into the following groups: dislocations and anomalies, primary organic stenosis, secondary stenosis and functional stenosis. According to this grouping gastric dilatation is capable of primary occurrence as an independent disease or it may occur secondarily in which case it must be regarded as purely symptomatic.

The condition of acute dilatation of the stomach is demonstrated on roentgenograms taken upright, supine and in lateral decubitus with or without peroral barium. The dilated stomach with fluid level or levels is visualized.

The group of dislocations and anomalies included a case of gastric volvulus, 2 cases of diaphragmatic hernia and a case of arterioesophageal obstruction. The group of organic stenoses of the stomach included 5 cases of pyloric obstruction and 2 cases of acute phlegmonous gastritis, which showed marked dilatation of the stomach. The secondary dilatations of the stomach included several cases due to inflammatory processes in the vicinity of the pylorus such as cholecystitis and pancreatitis.

Clinically many of the cases of gastrectasia simulate perforated ulcer, ileus, or volvulus of the bowel.
FRANK L. HUBERT M.D.

Röntgen Considerations of Pyelonephritis in Small Kidneys. EDGAR P. FENDERGRASS, RICHARD H. CHAMBERLAIN and FRANK P. BROOKS. *Am J Roentg* 1948, 59:165

The newer discoveries in regard to the relationship between renal pathology and arterial hypertension have created considerable interest as to the significance of unilateral small kidneys. In interpreting urograms the authors for some time paid attention not only to the gross morphologic changes but to the physiologic and pathologic abnormalities as well. They now report on the result of such analytical observation in the unilateral small kidney with special reference to the findings in atrophic chronic pyelonephritis.

The following scheme of analysis was pursued by the authors:

1. Gross anatomy of the kidneys
 - a. Position, size, shape and axis of the kidneys
 - b. Density of the kidney shadow
 - c. Delineation of the kidney from surrounding structures
 - d. Mobility of the kidney as a whole
2. Roentgenologic quality of clearance of the contrast media
 - a. Selection of contrast medium for testing of tubular or glomerular function or both
 - b. Comparison of clearance from both kidneys
 - c. Comparison of urea clearance with skidodan excretion
 - d. Determination of delay in excretion
3. Anatomy of the renal pelvis and calices
 - a. Number and configuration of the calices
 - b. Character of the filling
 - c. Position of the renal pelvis, intrarenal or extrarenal
 - d. Relative proportion of the medulla and cortex
4. Physiology of the renal pelvis and calices
 - a. Character of the peristalsis
 - b. Elasticity of the pelvic structures and consideration of the reversibility of any dysfunction
 - c. Disturbance in emptying

Pathology of unilateral small kidney. A significant smallness in size of a kidney may be the result of malformation in development, of atrophy from acquired disease or of both. It is not possible to make the distinction between the two types clinically. It was hoped that roentgenologic means might lead to a better result. However the differential features in certain cases appear too subtle to be of value although pertinent indications as to the nature of the abnormal kidney may be shown.

Hypoplasia of the kidney. This is defined as a kidney which is small as a result of defective development but which contains functioning normal tissue. Its incidence at autopsy has been quoted as varying between 1.000 and 2.3,000.

Acq. red atrophy. The most important diseases responsible for an acquired unilateral renal atrophy are (1) atrophic chronic pyelonephritis (2) primary atrophy and (3) pyonephrosis.

Atrophic chronic pyelonephritis represents the most frequent cause. Hage, for example, reported 69 contracted pyelonephritic kidneys in 9,888 autopsies. The mode of its pathogenesis is difficult, if not impossible to evaluate by any means except for the classical division into the ascending and hematogenous forms. The basic pathologic change of a small pyelonephritic kidney is characterized by cortical scarring which has replaced glomerular and tubular structures with corresponding thinning of the cortex. On urographic examination this change is manifested by the demonstration of fixation, loss of elasticity and loss of peristalsis.

A primary atrophy of the kidney is observed rarely. It may occur in anuria from obstruction, but the unique mechanism of hydronephrosis is the usual reaction of the kidney to such obstruction.

Pyonephrosis is defined as a secondarily infected hydronephrosis. The small kidney resulting from this condition is indistinguishable pathologically and roentgenographically from atrophic chronic nephritis.

Röntgenologic considerations. This division of the origin of the small kidney appears to be rational but, from the roentgenologic standpoint, there are the following interesting observations which are difficult to explain: (a) the small kidney with or without urographic evidence of pyelonephritis found on the first examination in every case studied by the authors except one which showed a small diminution in the size of the kidney after 4 years; (b) the fact that the condition has occurred in both children and adults; (c) many cases of pyelonephritis are observed in which the kidneys are not small, and in bilateral pyelonephritis only one kidney has appeared to be small in practically every instance; and (d) small kidneys, presumably hypoplastic, were observed in patients in whom there was no clinical evidence of disease.

The authors found altogether approximately 60 cases of unilateral small kidney. In addition to the diminution in size there was often an unusually sharp demarcation of the renal contour from the surrounding soft tissue densities. The mobility of the kidney as a whole was restricted in many cases, such fixation probably being the result of capsular inflammatory changes. The ability to clear the intravenous contrast medium was frequently impaired.

Some information was also gained from a study of the anatomic aspects of the renal pelvis and calices, from an evaluation of the relative proportion of the medulla and cortex of the kidney, and from a serial examination of the physiology of the renal pelvis and calices in the supine Trendelenburg and semierect positions, best accomplished with the excretory contrast method.

Ten illustrative cases are briefly reported with reproduction of the respective roentgenograms.

T. LECOMTE, M.D.

Bone and Joint Lesions in Leprosy A Radiologic Study GONZALO ESCOBARRA GÓMEZ and EMILIO ACOSTA. *Radiology* 1948 50 619.

An extensive roentgenographic analysis was made of the hands and feet of 532 patients. Of this group 483 were known to be afflicted with leprosy 5 were suspects and 44 were normal.

The leprosy patients were classified according to the International Congress of Leprosy (1938) as neural or lepromatous (cutaneous) types. The two groups were subdivided as minimal, moderate or advanced with a mixture of the main groups as well.

Of the 483 leprosy patients, 365 were males and 118 females. The ages of patients ranged from infancy to 90, the incidence being greatest in patients between 30 and 50 years of age.

Decalcification and rarefaction, producing a vacuole appearance, were frequently observed in the epiphyses of the phalanges, and in the metacarpal and the metatarsal bones. In some instances the cortex expanded and ruptured under pressure. Vacuole appearance is due to nerve damage or to the growth of Hansen's bacilli in the bone marrow and osseous tissue. Decalcification may be caused by impaired circulation due to destruction of sympathetic fibers of the nutrient arterioles, nerve disorder due to poor condition of afferent nerves and disturbed calcium metabolism. The results of disturbed calcium metabolism remain contradictory and don't fulfil.

Hypertrophy and hyperostosis occur at the articular ends of the phalanges, the metacarpal or the metatarsal bones and produce deformities. In some instances the bony deformity is hooded.

Reabsorption may be of a simple type or may follow atrophy. It occurs in both the neural or cutaneous types of the disease. Simple reabsorption appears as an osteitis of the distal phalanges. Small erosions may be seen. This type of absorption begins with an onychia. The proximal end of the phalanx may become involved and produce an increased density and expansion of the phalanx so-called "hood." Eventually the bone is destroyed and the joint is involved.

Reabsorption following atrophy produces a thin distal phalangeal diaphysis which tends to become conical in shape. The appearance at one stage may resemble a collar button, eventually only the proximal portion of the phalanx remains with a hood image. Middle phalangeal involvement is characterized by a diabolical form. Fractures are frequent. Proximal phalanges show joint distortion and muscular atrophy.

Mutilation may affect all four extremities, stopping at the carpus and Lisfranc's articulation. Perforating plantar ulceration of the anterior inner aspect of the foot with bone changes suggesting osteomyelitis may also occur. However, epiphyseal location at the first metatarsal and proximal phalanx, plus soft tissue destruction, should be sufficient to warrant a diagnosis of leprosy. Healing takes place through ankylosis. Osteomyelitis (whitlow type) can

be differentiated from a true osteomyelitis by the absence of pain.

Of the 483 leprosy patients examined, 306 presented radiological evidence of involvement of the hands and feet. Of the remaining 177 patients, 68 per cent showed suggestive but not conclusive roentgen findings of leprosy.

MAURICE D. SACHS, M.D.

Atlanto-Occipital Fusion, Occiput Terminale and Occipital Vertebra as Related to Basilar Impression with Neurological Symptoms. LEX A. HADLEY. *Am J Roentg* 1948, 59 511.

The author presents 6 cases of congenital anomalies occurring at the foramen magnum. In 1 case the condition was an occipital vertebra, in 4 cases undoubtedly, atlanto-occipital fusion and in 1 case the features of both were present. In 5 of the patients, asymmetry with tilting of the head was shown and in 4 foramen distortion. Several other anomalies were present in these cases.

In occipital vertebra the atlas is present and the malformations surround the foramen magnum. There may be hypochondral arch partially or completely fused to the anterior margin of the foramen magnum, this may bear a third condyle for articulation with the odontoid. This condyle may be either an articular depression or a single tuberosity with an articular facet. Bilateral bony masses or accessory eminences may encroach upon the anterior part of the foramen magnum. These various bony tuberosities and masses develop in the ligamentous tissue about the foramen. A partial or complete neural arch may be outlined about the dorsal surface of the foramen. Transverse processes may or may not be present, more or less fused with the bones of the skull. If present they do not bear a foramen for the vertebral artery. The condyles resemble those of the normal subject and an occiput terminale may be present.

In atlanto-occipital fusion the differentiating value is the shape of the condyles. On the occipital vertebra these are oval and convex, and in the antero-posterior view their articular surfaces face laterally in a caudal direction. The condyles on the under surface of an assimilated atlas, however, are flattened and their surfaces visualized in the antero-posterior view are directed medially in a caudal direction. In a case of atlanto-occipital fusion the articulation above the atlas is lacking on one or on both sides. Flexion-extension studies will reveal a fixation of movement between atlas and occiput. The transverse processes bear foramina for the vertebral arteries. There is a space between the dorsal arch of the atlas and the occiput for passage of the suboccipital nerve and the vertebral artery. There is an articulation on the anterior arch for the odontoid. As with the occipital vertebra the accessory eminences on one or both sides may encroach upon and distort the foramen magnum. The anterior arch or the posterior arch may not be completely fused with the occiput. Nonsegmentation may have occurred only on one side.

Good stereoscopic roentgenograms are much superior to planigrams. A lateral survey film with the head at full limit of the forward flexion should detect nearly all cases. The foramen magnum may be visualized by either the vertex-occiput or the occiput-vertex projections with some distortion. Other films to visualize the odontoid process, the planes of the atlanto-occipital and the atlanto-axial articulations are taken.

Early operation offers the promise of arresting the progress of the condition, although restoration of normal relationships is impossible. If a congenital anomaly of the above types is discovered in a young child not yet showing symptoms, the parents should be acquainted with the possibilities and remain alert for the first appearance of neurological signs. These may not appear until the second or third decade.

FRANK L. HUMERY M.D.

A Method of Roentgenologic Examination of the Shoulder WILLIAM E. HOWES and B. BRUCE ALGARDEN, *Radiology* 945 50-562.

Routine roentgenograms of the shoulder girdle, namely, the anteroposterior views with the hand in external and internal rotation, in many instances are not adequate to warrant an accurate diagnosis.

Anatomic studies of the skeleton were made in an effort to determine the insertion areas of the short rotators and of the subscapularis tendon. It was soon obvious that the best way to demonstrate calcifications or chip fractures would be through the use of multiple tangential views. The following five views were found to be necessary:

1. To demonstrate the infraspinatus tendon, the shoulder is elevated at a 25 degree angle with the hand in external rotation.

2. To demonstrate the supraspinatus tendon the angle board is removed and the hand is held in supination.

3. To demonstrate the teres minor tendon the hand is held in internal rotation.

4. To demonstrate the subscapularis tendon (axillary view with the patient sitting) the arm is held in abduction, the central ray is angled medially and cephalad through the axilla.

5. To demonstrate the bicipital groove and tubercles the hand is held in supination and the main ray is directed from the elbow medially and cephalad at a tangent toward the bicipital groove.

By utilization of multiple tangential views accurate localization of calcifications or fractures can be established.

MAURICE D. SACHS, M.D.

Tumor Dose in Cancer of the Larynx. CHARLOTTE P. DOXLAN, *Radiology* 945, 50-453.

The technical factors, dosage and results of the treatment of cancer of the larynx reported by Blady and Chamberlain, Howes and Platan and Cutler are compared with those of the treatment of 113 patients with cancer of the larynx at the Radiotherapy Department of the Presbyterian Hospital, New York, from April 27 1938 to November 21 1944.

During this period the technique and dosage varied considerably in the author's series. In the latter part of this period, she used 200 kv. 25 ma. 50 cm. STD and 1 mm. of copper plus 2 mm. of aluminum filter were used. The average daily dose was 125 roentgens in air to each of two lateral portals 7 cm in diameter. Earlier she used 20 by 10 fields with an average daily dose of 350 roentgens in air.

The total tumor dose in the author's series and the various other reported series closely approximated 5,000 roentgens.

Comparison of the results obtained in the author's series showed very little difference between the techniques used in the earlier and later cases. The results of the various authors are also similar except that Cutler reports a larger percentage of 5 year cures with 400 kv. and two treatments daily.

VERNA W. RUTTEN M.D.

Mammary Cancer G. E. RICHARDS, *Brit. J. Radiol.* 1948, 249.

The author discusses some radiotherapeutic procedures currently used in the treatment of mammary cancer. These include (1) telerradium therapy (2) 200 kv. roentgen therapy and (3) 400 kv. roentgen therapy.

In 1933 the treatment of primary carcinomas of the breast by means of telerradium was commenced at the Ontario Institute of Radiotherapy in Toronto. A 4 gm. radium element (salt) unit was used. Concurrently a similar group was treated with 200 kv. roentgen therapy for comparison. In none of the patients so treated was cancer eradicated from the breast. This was rather disappointing especially as it concerns the radium but perhaps the small size of the beam limiting its usefulness to small primary lesions might explain the cause of the failure.

In 1938 400 kv. roentgen therapy was introduced. The skin and tissue reactions from this type of treatment were found to be much less troublesome and the method has resulted in eradication of cancer in 17 per cent of the cases, therefore the author is convinced that 400 kv. roentgen therapy has many points of superiority over either the telerradium or the 200 kv. roentgen therapy.

In the treatment of the primary tumor wherever possible 4 converging tangential portals of 10 by 20 cm. are used superior inferior medial, and lateral. Doses have been calculated for two planes (a) plane X, which represents the junction of the middle and outer thirds of the breast and (b) plane Y which represents the base of the breast just overlying the pectoral muscles. From the attached dosage charts it can be seen that if 200 kv. are used and a dose of 1,500 roentgens is administered per portal, plane X will receive a total of 2,430 to 3,240 roentgens whereas with 400 kv. and a dose of 1,800 roentgens per portal it will receive approximately 3,500 roentgens. Under identical conditions plane Y will receive a total of 1,870 to 2,240 roentgens and about 3,500 roentgens respectively. Since the average curicidal dose must reach approximately 5,000

roentgens the doses given must be considered despite the excessively severe skin reactions as still being too small to eradicate every cancer from the breast.

Treatment of the axilla. For this purpose 3 portals are used—an anterior, a posterior, and a direct portal into the axilla, with the arm abducted as fully as possible. With 3 such portals, each receiving 1,200 roentgens, the depth dose in the center of the axilla will be 2,000 roentgens which is too small. By using an additional superior portal directed downward from the point of the shoulder the dose in the apex of the axilla is raised to 3,500 roentgens. The results obtained by such technique amounted to 35 per cent.

Treatment of the supraclavicular area. Here tele-radium therapy is used to advantage. A 6 cm. circular beam is directed from several converging angles into the supraclavicular triangle effecting a fairly satisfactory crossfire technique. By this means 50 per cent of the palpable nodes were made to completely disappear. Next to tele-radium therapy in effectiveness is the 400 kv. roentgen therapy. With this agent 3 portals are used for cross-firing—an anterior oblique (which also includes the infraclavicular space), a superior lateral direct and a posterior oblique portal. A cone 6 by 8 cm. is employed the doses ranging from 900 to 1,500 roentgens per portal depending upon the individual skin tolerance.

Dosage charts are given (1) for the treatment of the primary tumor indicating (a) the dosages through plane X at 400 kv. and 200 kv. and (b) the dosages through plane Y at 400 kv. and 200 kv. and (2) for the treatment of the axilla (a) if 3 portals are used showing the dosages at 400 kv. and 200 kv. and (b) if 4 portals are used showing the dosages at 400 kv. and 200 kv.

T. LUCUTA, M.D.

The Influence of Castration with Roentgen Rays on Carcinoma of the Breast. VICO E. TRAYSER *Acta radiol. Stockh., 1948, 39, 189.*

The author compares the results of treatment of 99 patients with breast cancer and metastases or recurrences who were treated at the Radium Center in Copenhagen by roentgen ray irradiation over the ovaries with the results in a similar group of 100 patients who were not subjected to castration. The 99 patients were given both local treatment of the primary tumor and the metastases and roentgen treatment of the ovaries at some time or other after the appearance of the metastases whereas the 100 patients received only local treatment.

Of the 99 castrated 72 were treated with roentgen rays before the menopause, the remaining 27 were treated during the menopausal change or until 12 years after this period. The youngest patient was 26 years old at the time of castration, the oldest 59. All of the patients in the first group of castrates menstruated regularly but those in the second group had either shown signs of an incipient menopause or their menses had definitely ceased. The castration was accomplished with two routine doses of 250 roentgens on each of four fields (10 by 15 cm.) on the lower part of the abdomen—two anterior and two

posterior, with 180 kv., 15 ma. a distance of 40 cm. and a filter of 0.5 of copper. In 24 cases 1,000 roentgens were given to four fields but seemingly without greater effect than the other doses. There were metastases in all of the cases at the time of castration.

In the 100 noncastrated patients the treatment with roentgen rays to recurrences and metastases was essentially the same as in the castrated ones. The average age of the 100 patients was 45.6 years corresponding to an average age of 43.5 years for the castrates.

Of the castrated patients 40 per cent had a survival of 2 years or more after their appearance while the corresponding figure for the controls was only 11 per cent. After 5 years 20 per cent of the castrated patients were still alive while all of the patients in the control group had died. Of 74 who had received roentgen treatment before or after operation and had been castrated 28 per cent were alive 5 years after the operation as against 8 per cent of the controls.

On the basis of 79 urine assays 41 for gonadotropin and 38 for estrogen it was shown among other things, that the castration may have had a highly beneficial effect even in cases in which the estrogen output was low before castration.

Castration therapy is not certain to prove effective but it may be concluded that in one-third of the cases it will result in temporary improvement of the patient's condition. It may be the means of obtaining some additional years of life in relative comfort for the patient and it may also prolong life to some extent.

FRANK L. HURLEY, M.D.

Roentgen Treatment of Cancer of the Esophagus. JACOB R. FREID. *Am. J. Roentg.* 1948, 59, 551.

The author re-evaluates the present-day treatment of cancer of the esophagus and describes his experience with roentgen therapy at Montefiore Hospital. He reports the case of a patient who is well more than 7 years following roentgen therapy.

A review of the literature shows that in operable cases surgery is the treatment of choice. However since by far the majority of these growths are inoperable, roentgen radiation constitutes the most commonly used treatment.

Contraindications to the use of radiation therapy are (1) infection, (2) severe anemia, and (3) cachexia and emaciation.

The methods of irradiation include (1) interstitial radon seeds (2) intracavitary radium tubes (3) telecurietherapy (4) roentgen therapy and (5) the combined technique consisting mostly of an association of radium therapy with external roentgen therapy.

The factors governing the response of the esophageal carcinoma to irradiation are (a) radiosensitivity (b) clinical character of the neoplasm (c) stage of the disease (d) accessibility and (e) previous treatment.

At Montefiore Hospital the following method of irradiation is used—200 kv. or 400 kv. (the latter

being preferred) 3 anterior and 3 posterior portals with the patient lying flat or being in a sitting position 100 roentgens with 400 kv to each of the six fields daily until a tumor dose of 6,000 to 7,000 roentgens is reached in 6 weeks or 500 roentgens with 300 roentgens to two or more fields, for a period of 6 weeks. Under ideal conditions the daily dose to the tumor should be approximately 200 roentgens and not less than 150 roentgens.

The complications and injuries include (1) severe changes in the lungs and mediastinum following intensive irradiation (2) dysphagia following well planned irradiation, which may be due to scar formation and contraction of the esophagus (3) aggravation of coexistent pulmonary and mediastinal tuberculosis and (4) perforation complicating fractionated roentgen therapy of moderate dosage. Examples of all these possibilities are given and illustrated with roentgenograms.

The number of patients treated was 23. With the exception of one, all received roentgen therapy exclusively. The average survival from the time of treatment amounted to 11 months as compared to the 5 to 8 months survival from the onset of symptoms quoted in the literature for nontreated patients.

Autopsies, some time after irradiation were performed on 4 patients. In 3 of the patients there was no evidence of carcinoma, and in the fourth patient only a few degenerating carcinoma cells were found. The one patient who is well after a period of 7 years is from the author's private practice. This case is described in detail.

A bibliography of 23 articles is appended.

T. LEUCOTIA, M.D.

Primary Tumors of the Small Intestine. CARROLL C. DUNDON. *Am. J. Surg.* 94:8, 59-69

The author reviews 62 cases of tumors of the small bowel from the records of the University Hospitals of Cleveland, for the years 1913 to 1946.

Eighteen cases of malignant tumors were recorded in 13 of these the patients had symptoms referable to the gastrointestinal tract, or had a palpable mass in the abdomen. The incidence was 1 tumor to 3,000 admissions on the surgical service, or 1 tumor to 9,000 general hospital admissions.

There were 44 benign tumors only 2 of which caused clinical symptoms these 2 were pedunculated and caused intussusception.

Of the 18 malignant tumors, 3 were found in the duodenum, 8 in the jejunum, and 7 in the ileum. (Tumors of the ampulla of Vater are not included in this report.) There were 12 carcinomas—3 in the duodenum, 5 in the jejunum and 4 in the ileum. Two lymphosarcomas and 1 leiomyosarcoma occurred in the jejunum. One fibrosarcoma and malignant carcinoids were found in the ileum.

The average age of the 8 patients with malignant tumors was 45 years, and the age range was from 21 to 76 years. There were 10 males and 8 females. The chief complaints of the 18 patients with malignant tumors of the small intestine were

abdominal pain in 9 cases, vomiting in 2 cases, and diarrhea and weakness in 1 case each.

Six patients had no symptoms referable to the gastrointestinal tract, although 1 of these had a large abdominal mass. Abdominal pain existed in 9 of the 18 patients for an average period of 11 months. Nausea and vomiting occurred in 5 patients, with an average duration of 11 weeks. Mild and intermittent diarrhea existed in 3 cases for an average period of 9 months. Five patients had melena in 2 of these the melena was severe having appeared as a terminal event and as the immediate cause of death. Intussusception occurred in 4 cases. A tumor mass was palpable as an abdominal mass in 6 patients. Loss of weight was severe in most cases.

Eight of the malignant tumors were infiltrating in type and 9 were polypoid. Three of the polypoid tumors were pedunculated.

Necrosis of the tumor with ulceration and hemorrhage developed in 5 cases.

Both of the patients with lymphosarcoma had no foci of involvement.

Metastases or local extension to adjacent organs had occurred in 16 cases when the tumors were discovered. Distant metastases of the lung and brain were found in 1 case each before the primary tumors were discovered.

A review of the roentgenograms revealed definite changes in 8 cases which might have led to a correct diagnosis if complete studies had been made.

Eight patients had barium studies. Four showed narrowed loops of small intestine 1 had complete obstruction to the passage of barium through the jejunum 1 showed dilatation of the intestine at the site of the lesion and 1 patient had marked hypermotility.

The author states that patients who have persistent abdominal pain, either intermittent or constant, and patients with vomiting, melena, or diarrhea which remains undiagnosed after routine studies of the gastrointestinal tract, gall bladder, and urinary tract, deserve special study of the small intestine to exclude a primary tumor.

FRANK L. HURST M.D.

Röntgen Treatment of Multiple Myelomas. L. HENRY GARLAND and BAILEY R. KENNEDY. *Radiol.* 27: 948, 50: 297

The authors review the literature and the results in a series of 13 cases of multiple myeloma which were treated by the use of roentgen therapy to determine the value of this type of therapy. Eight of the cases were proved microscopically and 5 had sufficient clinical, laboratory and x-ray evidence for the diagnosis. Six of the patients treated showed improvement in their condition, 6 were not appreciably benefited, and one had incomplete treatment. One of the patients survived more than 9 years and is still living. The average survival for the remaining treated patients was 14 months, while that of the untreated patients which the author mentions as 23 months.

The physical factors were as follows: 200 kv. half value layer of 1.8 mm of copper. The target skin distance and field size varied according to the sites treated (commonly used distances were 70 cm. and the fields were 30 cm. in diameter). The dose in roentgens was measured in air without backscatter. The dosage that the patients received varied considerably. It is believed that adequate irradiation of patients with multiple myeloma is still worth attempting.

Multiple myeloma is not a radiosensitive disease. Solitary myeloma appears to be radiosensitive and a radio-controllable disease in certain instances and should be treated by vigorous roentgen irradiation when the diagnosis is established microscopically. Multiple or solitary myeloma with spinal cord compression and paresis or paraplegia appears to be well worth irradiation (following laminectomy). In the literature survivals for as long as 7 years have been recorded.

FRANK L. HURSEY M.D.

Roentgen Therapy in Traumatic Myositis Ossificans. ERNST A. PUNZ and CAROL TOMLINSON
Am J R X 1948 215 372

The authors review the etiology, pathology, pathogenesis, and clinical findings in traumatic myositis ossificans.

After pointing out that early surgical removal is usually contraindicated because of the possibilities of recurrence, they describe their technique of roentgen therapy for this condition. With 275 or 400 kv. 50 cm. focal skin distance (half value layer of 3.05 mm. of copper and 2.4 mm. of copper) they deliver doses of from 150 to 200 roentgens in air in one or two fields daily or every other day for 3 or 4 treatments. A second series in from 4 to 6 weeks was given in some cases and a third series in from 2 to 4 months after the first course was occasionally necessary.

They have treated to patients with relief of pain in all of them. This was often noted 2 or 3 days after treatment and always after from 4 to 6 weeks. In most of the cases there was a slight decrease in the size of the calcified area. Limitation of motion showed marked improvement.

The authors believe that these beneficial results in a small series justify further trial of roentgen therapy in traumatic myositis ossificans.

JOHN O. LATTERTY M.D.

Lymphoid Tumors. HUGH F. HARRIS, WILLIAM C. MERRILL and C. FRANKLIN SORRENTINO
Radiology 1948 50: 561

The authors believe that early diagnosis and treatment of lymphoid tumors constitute the only approach to success in the treatment of lymphoid tumors. In a series of 151 cases diagnosed clinically and histologically as lymphoid tumors during the years 1914 to 1947 inclusive, 40 patients (26 per cent) were living and well at the end of 5 years and 2 others were living with recurrence of their disease. During the period of observation 30 per cent of the

patients had recurrent involvement of nodes locally or at a new site requiring treatment. Thirty seven, or 71 per cent of the 52 patients living, showed no recurrence following the initial treatment during the 5 year period of observation. The results then would indicate that if the disease is adequately treated when localized a significant number (29 per cent) will obtain a 5 year survival.

The onset of lymphoid tumors is insidious. In approximately 61 per cent of cases it is first noted as an enlargement of the lymph nodes in the neck. The enlarged nodes frequently follow an upper respiratory infection and subsequently recede only partially or not at all. The disease may originate in any part of the body and may become generalized before diagnosis is considered. It is important that a biopsy specimen be taken in each instance as soon as the nodes are discovered. All of the enlarged glands in cases of Hodgkin's disease do not reveal evidence of the disease. Roentgen therapy may be used as a method of diagnosis when the nodes are not accessible for biopsy.

Irradiation of localized lymphoid tumors must be directed in all palpable nodes and to the area surrounding the tumor bed with a total dosage of 2,400 roentgens delivered to the tumor 300 kv. with copper filtration, half value layer 1.6 mm. copper is used. Mediastinal involvement may be of the sclerous type, and at least 1,200 to 1,500 roentgens should be delivered to the tumor in the first course to establish the diagnosis. Two weeks after treatment comparative roentgenograms are made and if the lesion is considered to be radiosensitive treatment in the fullest extent should be carried out. Localized disease of the gastrointestinal tract is the most amenable to surgery. The treatment of generalized disease in most instances is for palliation only. 1,200 to 1,550 roentgens measured in air is usually sufficient in relieving about palliation and shrink the nodes enough to relieve pressure symptoms. Supportive measures and treatment of other symptoms should also receive attention.

FRANK L. HURSEY M.D.

Engelmann's Disease. H. R. SEAR
Br J Radiol 1945 21 236.

The rare congenital bone dystrophies associated with osteosclerosis fall into five main groups as represented diagrammatically in Figure 1. They are:

1. Osteopetrosis or marble bones
2. Engelmann's disease or osteopathia hyperostica scleritiformis multiplex infantilis
3. Melorheostosis or Leri's disease
4. Osteopoeclia or spotted bones
5. Punctate epiphyseal dysplasia or spotted epiphyses

Engelmann's disease is the rarest of these, this being the first reported case since Engelmann's single case in 1909. His case was that of an 8-year-old boy of whom roentgenograms showed bilateral symmetrical expansion and thickening and sclerosis of the diaphyses of all the long bones. No involvement

Fig. (Sear) Rare congenital bone dystrophies associated with osteosclerosis.

of the ends of the diaphyses or epiphyses was present. The skull showed thickened patches in the frontal bone and base of the anterior and middle cranial fossa, and thickening and sclerosis of the orbital roofs. The child showed a stature below normal with apparent lengthening and bowing of the legs, a short neck, flat feet, and lumbar lordosis. No other gross abnormalities were present and the history and laboratory studies were not significant.

Sear's case was that of a boy, years old of whom roentgenograms also showed dense osteosclerosis of the central portions of the shafts of the long bones, especially pronounced in the clavicles, forearms, femora, and tibia. The skull showed dense thickening and osteosclerosis of its base extending into the frontal bone. A history of some difficulty in walking from the age of 3 years was elicited and marked wasting of the leg muscles giving an apparent leg lengthening was noted. Biopsy showed very dense but essentially normal bone structure. Laboratory findings were not significant.

Engelmann's disease is differentiated from osteopetrosis, which gives a similar appearance in the skull by the central involvement of the long bones, sparing the ends of the diaphyses and epiphyses, and also by the absence of changes in the vertebral ribs, and bones of the hands and feet.

Infantile cortical hyperostosis of Caffey and Silberman is a disease of infancy characterized by and den onset fever asymmetrical bony involvement and slow return to normal. The mandible is most likely to be involved in the skull. The bone lesions are accompanied by painful soft tissue swelling. This is in contrast to the symmetrical involvement, changes in the base of the skull, and persistence of the lesion for 8 to 10 years which were seen in these

3 cases of Engelmann's disease, the rarest of the congenital condensing bone dystrophies.

Effects of Radioactive Sodium on Leucemia and Allied Diseases. T. C. EVANS, M. LEVY, C. P. DOTLAN and M. J. LEXLEY. *Am J Roentg* 94:3, 1960.

The authors present a report of the results obtained following the use of radioactive sodium in the treatment of 24 patients with leukemia and allied disorders. The amount of radiosodium excreted was found to be less than 10 per cent of the dose administered. The percentage of radiosodium excreted appeared to be related to the individual patient rather than to the amount of radiosodium administered, or to the amount of urine excreted. The distribution of radiosodium was determined by examining the tissues taken at autopsy from 3 patients who died about 48 hours after the administration of radiosodium. No marked concentration of radiosodium was observed in any of the tissues, although the concentration was somewhat higher in the vertebra, liver and kidney and slightly lower in the muscle and intestine.

With regard to the 5 preliminary cases in this series (1 patient in the terminal stage of Hodgkin's disease, 3 patients in the terminal stage of lymphoid carcinoma and 1 patient in the terminal stage of myelogenous leukemia) the results were such that the authors were encouraged to carry out additional studies on the treatment of chronic leukemia. Three patients with chronic myelogenous leukemia who had undergone previous radiation therapy and 4 who had

not had previous radiation therapy 4 patients with subacute and acute myelogenous leucemia, 2 patients with chronic lymphatic leucemia who had not had previous irradiation and 1 who had had previous leucemia, were treated. In this same series 1 patient with polycythemia vera and 1 with sympathetico-blastoma also were treated.

The final evaluation of radiosodium therapy can not be obtained from the limited number of cases in this series. Radiosodium however by mouth in a suitable quantity and taken at suitable intervals is effective in reducing symptoms of chronic myelogenous leucemia chronic lymphatic leucemia, and polycythemia vera. The rate of response of each treatment appears to be intermediate between that of roentgen therapy and treatment with radiophosphorus. The contraindications are similar to those for other forms of radiation therapy. The response to radiosodium therapy is not good when the disease is acute the radioresistance of the abnormal cells is high and the hemopoietic system is already damaged.

FRANK L. HUSKEY M.D.
The Treatment of Keloids at Radiumhemmet, 1921
1941 Folke JACONSSON *Acta radiol* Stockh.
1948 29 251

Keloids are benign proliferative fibrous tissue overgrowths. According to current opinion they are not regarded as tumors. However the growth is often very tumorlike. Radium or roentgen ray therapy is the method of choice in the treatment of keloids. At Radiumhemmet 625 patients with keloids have been treated during 1921 to 1941. In 563 cases the keloid was confined to one part of the body. In 62 patients keloids were distributed on two or more parts of the body. There was a preponderance of women. In 112 cases the keloid had earlier been surgically excised

one or more times with subsequent recurrence. Five hundred and forty nine patients were treated with radium 124 with radium and roentgen and 25 exclusively with roentgen. The keloid was excised in 27 cases and then within 10 days the scar was physiologically irradiated.

In the use of radium clinical experience has shown that conformity between dosage and skin reaction will be found if the dose has been calculated in accordance with the average of the intensity at a central surface point and at each successive point down to the depth of 1 cm. The dosage now is always calculated as average dose in 1 cm. tissue layer. According to Strandquist this dose is approximately the same as the dose at a depth of 3 mm. under the surface. The unit of radiation intensity chosen is 5 units per hour having a value of 7.5 roentgens per hour equivalent to 1 millicurie. The dosage since 1936 has varied between 600 and 1 200 roentgens usually between 850 and 1 000 roentgens. As an example of the treatment time it may be mentioned that 900 roentgens are delivered in 2 hours by an applicator containing 10 needles (100 mgm. radium) arranged in one row. Roentgen treatments were given to thick and large keloids not suitable for radium treatment. Sometimes single but usually divided doses were given. The total doses have been more than 1 000 roentgens (with backscatter) in 21 cases (in 10 more than 1 500 roentgens) and in 22 only one series of treatments was given. Care should be taken in keloids caused by burns. After total doses of more than 1 000 roentgens the skin seems to be easily damaged. The best results seem to be achieved if the keloid is of less than a year's duration. Total regression of keloid was obtained in 73.6 per cent considerable in 14.4 per cent evident in 9 per cent slight regression in 1.9 per cent and an unsatisfactory effect in 1.1 per cent.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Protein Deficiency JOHN D. STEWART, HARRY W. HALE, JR., and SHERMAN M. SCHWARTZ, *J. Am. Med. Ass.* 1943, 36 617

The present article is concerned with some of the practical aspects of protein nutrition in the surgical patient who may constitute a difficult problem because of his inability to eat due to various causes. Intravenous injection of whole blood, plasma, serum, and various prepared mixtures may be the only feasible method of supplying protein in quantity.

The requirements to be met by the solution of amino acids to be used intravenously are: (1) the aqueous solution must be stable and contain a suitable concentration of the essential amino acids; (2) it must produce only minimal changes in the acid base and water balance; (3) it must be nontoxic, nonallergenic, sterilizable, readily available, and inexpensive. The authors utilized a sterilized, aqueous, nonpyrogenic, 5 per cent solution of an enzymic hydrolyzate of purified casein and pork pancreas to which dextrose had been added in 5 per cent concentration. The hydrogen ion concentration was adjusted to a value of 6.5. A liter of the solution supplies 50 gm. of amino acids and 50 gm. of dextrose. It is given intravenously once or twice a day in no less than 3 hours per injection.

A variety of conditions in many patients (as much as 90 liters were given to a single individual over a period of 3 months) were treated with the mixture. The incidence of a toward reactions was about 6.5 per cent, the most severe of which seemed to be nausea and vomiting. A point of importance for the severely dehydrated acidotic patient is the occurrence of a definite lowering of the carbon dioxide combining power of the plasma after its administration in quantity. In a considerable experience the authors have found nothing to contraindicate casein hydrolyzate therapy in the presence of grave hepatic disease. Charts are presented to substantiate this statement. The need for other essential dietary constituents such as calories, vitamins, and minerals, among others, must be kept in mind.

For patients with lesions of the upper gastrointestinal tract, intrajejunal feeding is recommended. A jejunostomy may be a modified Witzel technique, made from 18 to 24 inches beyond the ligament of Treitz under local anesthesia, and with a 16F catheter was done by the authors. A satisfactory mixture for jejunal feeding must meet the following requirements: (1) the mixture should be complete with adequate amounts of the elements of the normal diet; (2) it should be fluid enough to drip by gravity through a small catheter; (3) it should be neutral in reaction and contain enough colloid to protect the intestinal mucosa against irritant salt action.

(4) it should be easily prepared, inexpensive, capable of being varied to meet individual needs, and should keep at least 48 hours under refrigeration; and (5) it should yield a low residue and be easily digested and absorbed. A formula, utilizing water, sucrose, casein, yeast, trypsin, vitamins and minerals, is given in detail as well as the chemical analysis which it yields. This mixture is given each day over a 12 hour period in 3 or 4 ounce injections every half hour. Cramps, nausea, and diarrhea may occur if too much is given at one time. This method has been utilized in the alimentation of patients with a variety of conditions including obstructive jaundice and hepatic damage. A brief discussion follows the paper.

The Mechanism of Delayed Death following Thermal Trauma. H. C. BROMMAN, H. E. KROGER, and ALFRED PRINCEMETAL, *J. Lab. Clin. Med.* 1943, 33 504

The authors performed experiments on mice and rats to determine the mechanism of delayed death following thermal trauma.

Previous observations have shown that burn shock was accompanied by a reduction in the circulating blood volume as represented by the bleeding volume, and that two major factors were implicated in this reduction: (1) local fluid loss, and (2) atony of the vessels comprising the capillary bed of the visceral organs.

The bleeding volume was ascertained by removing the heart and mopping up the blood entering the thoracic cavity with weighed cotton pledgets. The presence and degree of capillary atonia were determined by measuring the amount of hemoglobin retained in the liver. The techniques and methods employed are described in detail.

Observations showed that a number of animals died at various time intervals: 300 mice scalded to the head in water at 60° C. for 7 seconds and 80 rats scalded to the head in water at 65° C. for 10 seconds died from the second day to more than a month later. This investigation was undertaken primarily to determine the bleeding volume and the degree of capillary atony in surviving animals in an attempt to elucidate the mechanism of delayed death after thermal trauma. The experimental results are recorded in a series of graphs. The observations were begun 2 hours after the burn and continued for 37 days.

In mice capillary atony and a decreased blood volume were demonstrated during the period in which the symptoms of shock were present. Upon the subsidence of these symptoms (generally within 24 hours) the blood volume was restored to its normal value, the capillary atonia disappeared and there was no further reduction in blood volume or reappearance of visceral congestion throughout the period of observation.

In experiments on rats after similar thermal trauma the bleeding volume showed a small but insignificant increase above normal 27 days after the burn. The authors concluded that delayed death after the type of thermal injury employed is not due to persistent or recurrent shock.

JOHN H. MOHARDT, M.D.
HILNIBCKER, *Surgery* 1948 23, 618.

The Pathogenesis of Diastolic Hypertension, PETER

A concept of the pathogenesis of diastolic hypertension which has evolved from an understanding of kidney homeostasis and from studies of patients with Cushing's syndrome is presented. There is an extensive review of experimental evidence, chiefly in the dog, which is pertinent to the problem. Denervation of the neural hypophysis in the dog results in a preponderance and overaction of eosinophile cells in the glandular hypophysis. With marked depression of the secretion of the neural hypophysis a normal cardiac output is maintained and a moderate elevation of the mean arterial pressure develops. These changes also occur when the nervous pathways from the thalamus and subthalamus to the paraventricular and supraoptic nuclei are interrupted, when asphyxia in one adrenal gland is produced by ligation of a portion of its arterial supply when a diminution in the amount of effective renal tubular tissue is produced by removal of one kidney with the wrapping of the remaining kidney in silk, when mulberry-like ovaries are produced by prolonged administration of thiostation their common factor of eosinophile overaction is considered to be significant as a causative factor in the development of hypertension.

These eosinophile cells are trophic to the adrenal gland renal tubules and to the interstitial tissue of the gonads. Loss or depression of the secretion of the neural hypophysis results in sensitization of the blood vessels to epinephrine, desoxycorticosterone and to renin. Under certain conditions of depression of the neural hypophysis there is increased output of the last two of these hormones the blood vessels are sensitized and hypertension results.

In certain cases of Cushing's syndrome an overaction of the eosinophile cells may result. The effects of hypertension and arteriosclerosis invariably produced are considered to result from a narrowing of the extrarenal blood vessels and of the efferent glomerular arterioles. Renin is released as a result of the latter action. It is to the combined action of these hormones in persons whose neural hypophysis is depressed and whose blood vessels are therefore sensitized to the constrictive action of these hormones that hypertension is attributed. There may be a constitutional susceptibility in addition.

The development of arteriosclerosis may be traced to the overaction of the eosinophile cell adrenocortical hormone and to the storage of neutral fat and cholesterol.

The reaction of the body to any inadequacy in renal tubular function is regarded as resulting in hypertension. Renin is regarded as the substance released by the kidney tubules, which not only constricts vessels outside of the kidney directly, but also stimulates the eosinophile cells and thereby increases the cardiac output and renal tubular function. In combination with the desoxycorticosterone fraction of the adrenocortical hormone it leads to extrarenal vascular constriction.

The depression of the neural hypophysis in persons with essential hypertension is regarded first as functional because of nervous influences, particularly from the frontal lobes later in the malignant phase it may be organic as well because the increased intraventricular pressure acts on cells of the supraoptic and paraventricular nuclei.

Constitutional susceptibility of the nervous system to the depression of the hypothalamic nuclei and of the blood vessels to the constricting action of the hormones responsible for the extrarenal vasoconstriction is postulated for essential hypertension.

Inactivation of the secretion of the neural hypophysis by progesterone is regarded as resulting in the eosinophile cell preponderance in pregnancy. This stimulates the adrenal glands and in those persons who are emotionally and constitutionally susceptible it would be expected to result in sufficient constriction of the efferent glomerular arterioles to release renin. As in essential hypertension the combined action of these hormones together with the action of progesterone on vessels sensitized by the depression of the neural hypophysis, is regarded as primarily responsible for the initiation of diastolic hypertension.

The accepted importance of emotional influences in the development of essential hypertension is regarded as support of the concept of its pathogenesis as described by the author. The frequent association of obesity of premature ageing of decreased insulin sensitivity and of increased intracranial pressure particularly in later stages of essential hypertension is considered to support the probability of the hypothesis presented. Additional support is interpreted as being derived from the fact that the characteristics of the circulation of essential hypertension are similar to those which exist in the hypertension associated with Cushing's syndrome. In which such a mechanism has been established in essential hypertension the sympathetic nervous system and epinephrine are believed to produce rapid homeostatic adjustments of the renal circulation but they are not considered of primary importance in the pathogenesis of such hypertension. The author believes that his concept affords a mechanism for explaining the prevalence earlier and wider incidence of hypertension and arteriosclerosis in response to the stress and strain of modern existence.

The interested reader is advised to read the article in detail for the comprehensive review of the pertinent experimental evidence in support of the author's concept as well as the interesting diagrams illustrating

ing interrelationships which may exist between the many factors playing a part in the pathogenesis of hypertension

ALLAN D. CALLOW, M.D.

The Effects of Shock on the Kidney DONALD D. VAN SLYKE, *Ann. Int. M.* 94, 18, 70

Present concepts concerning the effects of shock on the kidneys have developed from the studies of many investigators. During World War II Bywaters and his collaborators reported on the effects of crush and compression injuries with uremic death in a series of cases following burial or pinning beneath falling debris in air raid casualties.

The author outlines the experimental and clinical studies of importance concerning the effects of shock on the kidneys and contributes the results of new experiments on kidney function and pathology initiated by a decreased volume of the circulating blood.

The type of shock here discussed is the condition caused by hemorrhage, burns, trauma, dehydration, or other injury in which there is an inadequate volume of blood to fill the vascular bed. However, the present discussion is limited to conditions of shock in which the decreased volume of circulating blood is due to blood or plasma loss or from dehydration.

The immediate and late effects of shock on the kidneys, based on available data, permit the following conclusions. The immediate effects of shock on the kidneys are circulatory. Renal blood flow is diminished and with it renal excretory function. The decrease may be so great that complete anuria results. However, if the renal ischemia is not too complete or prolonged the kidney cells are not irreversibly injured, and restoration of a normal general circulation is followed by recovery and normal renal function within a short time. The initial shutdown of the renal circulation appears to be a part of a defense reaction of the organism to loss of circulating blood volume; the vascular bed is contracted by peripheral constriction so that the diminished volume of available blood will be adequate to supply the vital organs such as the brain, the function of which must be maintained to avoid immediate death.

If shock is severe and prolonged, restoration of the general circulation and recovery from the circulatory symptoms of shock may not be accompanied by resumption of normal renal excretion. Anuria or oliguria may persist, or urine of low specific gravity may be excreted. This period of complete or partial renal failure may last until fatal uremia develops in a period that may vary from 2 to 20 days, or gradual return of function may occur so that the excretion becomes sufficiently restored to prevent uremia, and ultimately recovery of the kidneys may be complete.

Shock must be severe and prolonged to cause irreversible changes in the kidneys, but if it is too severe it causes death from circulatory failure before the patient has had time to develop uremia. The inability to stop the progress of uremia of severe or prolonged shock was a major concern to surgeons in the late war. Renal failure persisting after shock is due to organic injury initiated during shock by ischemia.

Histologic studies by Bywaters and his colleagues (Lucke, Mallory and others) have revealed severe damage to the renal tubules, mainly the distal tubules and loops of Henle, with little or no glomerular damage, as a constant finding in postshock uremia. The presence of hemoglobin derivatives which formed in the tubules one or more days after onset of renal failure was also noted; this may contribute to the progress of tubular damage initiated by ischemia. The tubular lesions suggest that the cause of post shock uremia may be not the failure of glomerular filtration but the tubular reabsorption of glomerular filtrate and its excretory constituents.

To diminish the danger of death from postshock uremia, the following procedure is emphasized: (1) cut the duration of shock as short as possible by quick restoration of the blood volume through adequate replacement of the lost blood with plasma or saline solution; (2) if acidosis is present, either during or after shock, administer adequate amounts of bicarbonate of soda; (3) while the administration of large amounts of fluid may be necessary to obtain normal blood volume and hydration, over-administration is to be avoided both during and after shock as circulatory embarrassment may be caused. The measuring of the specific gravities of blood and plasma, preferably by the copper sulfate method, is of practical assistance in planning and guiding fluid administration; (4) when after recovery from acute shock anuria or excretion of urine of low volume and specific gravity persists and the blood urea continues to increase, a diet high in carbohydrates and fat, and low in protein should be prescribed to retard accumulation of catabolic products; and (5) it appears that vivification and peritoneal and gastrointestinal irrigation may overcome the uremia and favor recovery of the renal function. JOHN H. MOWAT, M.D.

Hemangiomas: an Evaluation of Treatment by Injection and Surgery NEAL OWENS and KATHERINE L. STEPHENSON, *Plast. Reconstr. Surg.* 1943, 1, 99

Hemangiomas generally pursue a benign course but if untreated, frequently grow more rapidly than commonly suspected, and thus produce cosmetic deformities. Occasionally there may be rapid acceleration with destruction of an important anatomic part such as the eye, nose, ear, lip, cheek, neck, or a large portion of the skin of the scalp, neck, back, and extremity may become involved. Ulceration and secondary sepsis may become the problem. When rapid growth takes place as in the aggressive hypertrophic type, it is fundamental immediately to consider surgical excision in order to avoid further destruction, unless one elects injection therapy. Establishment of a positive diagnosis by biopsy is one excellent reason to elect surgical excision in contrast to injection. Rarely one may encounter a case which on biopsy may appear benign histologically but which, as subsequent history discloses, is malignant due to metastasis. Occasionally the growth may become diffuse and involve an entire extremity or establish connection with a large blood vessel and become destructive.

tive or dangerous because of severe hemorrhage. In many instances the apparently discrete areas may be deceptive in that their extension can be remote to the area defined by the slightly raised red tumor.

The female is affected two to three times as often as the male. Although no acceptable explanation for this higher female incidence has ever been offered, Watson and McCarthy have suggested that hemangiomas may in some fashion be related to the female sex hormone and in this connection it is of interest to note that a hemangioma may start or increase rapidly in size with the onset of the menses or at the beginning of pregnancy.

It is generally accepted that hemangiomas are tumors of independently growing blood channels with their origin in embryonic rudiments of mesodermal tissue. The vascular channels, their arrangement and the amount and character of the surrounding stroma are the most logical basis for classification. Angiomas may develop in capillaries and exhibit a capillary structure. Or they may be composed of large lacunae usually with venous connections (rarely arterial) surrounded by very little stroma.

Rarely there are certain of these tumors that are microscopically similar to the ordinary benign capillary or cavernous hemangioma and yet metastasize. When they involve the internal organs extensively they are the cause of death of the patient and thus are malignant. This group is not well defined. Much confusion has arisen in this regard and there are few authentic cases on record.

For the purpose of clarification the following chart based on Foot's classification is presented:

Capillary hemangioma	{ (minimal supporting stroma)
Cavernous hemangioma	
Metastasizing hemangioma (cavernous or capillary)	
Sclerosing fibrous hemangioma	{ (periendothelial hyperplasia)
Hemangioendothelioma	
Angiosarcoma	{ (aberrant pleomorphic vessels with complete supporting stroma)
Arteriovenous hemangioma	
Cavernous hemangioma	

In the treatment of hemangiomas the authors have limited themselves to the use of surgical excision and the injection of a thrombotic material. In almost all types of hemangioma injection therapy is indicated and surgical excision is to be selected when there is danger of infection or if hemorrhage, malignant degeneration or carcinoma is present. Injection therapy is a particularly important method in those cases in which surgical excision to effect a cure would be impractical. In a part such as a nose ear lip or perhaps the center of an orbit. In these areas a cure resulting from a thrombotic material is often the desired therapeutic result with a minimum of damage to the part affected.

Small tumors of a few centimeters in diameter may be treated by means of curettage or excision. In the treatment of large tumors of the face, neck, trunk, and extremities, the use of a large area of excision followed by coverage with a free flap or a pedicle flap is often the best method of treatment.

the office over a period of months. The decision should not be made without careful consideration of the tumor location, the availability of tissue for repair, ease of surgical excision, and the possibility of complete eradication by one surgical maneuver.

LOUIS T. BARR, M.D.

Cancer Mortality in Egypt MAHMOUD AHMED AFRIT *Cancer Res.* 1948 7 537

The reported cancer mortality rate in Egypt in 1942 was 27.2 per 100,000 inhabitants or roughly a fourth of that in the United States and a seventh of that in England and Wales. This is in marked contrast to the death rate from all causes which is about three times that of the United States or England and Wales. In this article the author discusses the shortcomings of the information on which the cancer mortality rate is based. Only a third of the population of Egypt lives within the area where deaths are formally registered. Only half of the death certificates filed for this area list a cause of death. In the majority of instances in which a cause of death has been listed there has been no opportunity to ascertain the diagnostic accuracy of the certificate. The author believes that many deaths from cancer may have been listed under some other causes.

Analysis of data for the 12 year period from 1931 through 1942 show that the most frequent site of fatal cancer was the male genital organs with 1,451 deaths out of the total of 12,606. Malignancy of stomach and duodenum accounted for 1,337 deaths. The next two most common sites of fatal cancer were breast and uterus with 1,220 and 1,216 deaths respectively for these organs. Although the breakdown of the whole group of cancer deaths by sex, age, race, and religion as well as by the section of the country from which the death was reported seems to show very significant differences, the author is inclined to attribute many of these differences to poor reporting and certification of death.

There has apparently been no occupational cancer in Egypt nor has there been any cancer resulting from radiotherapy. However, there has been a high incidence of cancer in conjunction with bilharzias, especially that of the bladder. Since this disease affects from 30 to 60 per cent of the population of Egypt it is difficult to evaluate the causal relationship between it and cancer; indeed the author doubts whether there is a causal relationship.

BENJAMIN F. LOEWENBERG, M.D.

DUCTLESS GLANDS

Interpretation of Estrogenic Therapy of Cancer of the Breast (and Prostatic Glands). The Elective Effect of Estrogens on Mesenchyma and Its Importance (Interpretazione della terapia estrogenica del cancro della mammella [e del la prostata]. Azione elettiva degli estrogeni sul mesenchima e sua importanza). C. SERRA and R. CHATTAI. *Atti della Accademia Nazionale dei Lincei* 1947 33 519.

It is concluded that the use of estrogens in the treatment of cancer of the breast, favorably influenced by estrogenic therapy, did not dem-

onstrate regressive alterations in tumor cells but showed a substitution of connective sclerotic tissue by one rich in blood vessels, fibrillae and histiocytic formations.

The hard consistency of tumors and their fixations are caused according to the authors, by the character of the stroma rather than that of the neoplastic cells.

Modifications of the stroma caused by the estrogenic therapy are responsible for the reduction of the size of the tumor its increased mobility the ceasing of pains, and recurrence of canalization such as may be observed in carcinomas of the prostate gland.

Observations on patients and experimental studies revealed to the authors the elective hyperplasogenic effect of estrogens on the mesenchyma.

The observations were made on a young woman, 2 women in the menopause and a man. Fibroadenomas and biopsies of the skin were studied in patients who underwent the treatment with estrogens and in control persons.

The stimulation of the mesenchyma by estrogens is more intensive whenever an abnormal activity of the tissues, caused by ulcers or foreign bodies, is present.

The effect of estrogen on cancer of the breast is different in women during active sexual life from that in women in the menopause. In the first group a large number of fibrillae develops and the connective tissue appears soft, while in older women a fibrous, hard stroma much poorer in cells results from estrogenic therapy.

JOSEPH K. NARAY, M.D.

The Neuroendocrine Regulation of the Intestinal Absorption of Glucides (La régulation neuro-endocrinienne de l'absorption intestinale des glucides). ANDRÉ SOULAIRAC. *Ann endocr. Par.*, 947 8: 377

The author has completed an experimental study in the rat on the action of the endocrine glands and certain nervous mechanisms in the regulation of the intestinal absorption of glucose and glucides.

Experimental evidence would suggest that such absorption is controlled by hormonal activity of the islets of Langerhans the thyroid, the adrenal and the hypophysis. From the work presented it would seem that the action of these hormones is in turn dependent upon a hypophyseal-hypothalamic synergistic regulatory center.

This concept bears further investigation and may cast much light on certain nutritional problems and diabetic states.

EDWARD W. GIBBS, M.D.

THE PATTERN OF VASOSPASM FOLLOWING ACUTE ARTERIAL AND VENOUS OCCLUSIONS

A Micrometric Study

HAROLD LAUFMAN M.D., Ph.D., F.A.C.S. WAYNE B. MARTIN M.D., and
STANLEY W. TUELL, M.D. Chicago, Illinois

THE present study is concerned with the micrometric measurement of changes in caliber of the smaller radicals of the mesenteric vascular tree following occlusion of the superior mesenteric vessels. Our interest in the problem of vasospasm following vascular occlusions arose while studying the response of mesenteric vessels to intestinal strangulations (23). We were impressed by the importance of residual vasospasm in the involved vasculature following release of the strangulations at operation. Such vasospasm apparently had a marked influence on the recoverability of strangulated bowel. The study also showed that regardless of whether the strangulations were primarily venous or arterial vasodilating measures were of great value in resuscitation. From a review of the literature on the pathological physiology of peripheral vascular occlusion it appears that the mesenteric vessels behave no differently than the branches of mainstem vessels in other parts of the body following occlusions (2). Therefore our studies which were undertaken primarily to investigate the importance of vasospasm in intestinal strangulations have led us into much broader fields. The implications of our findings might

find application in the nature of most other vascular occlusions.

TECHNIQUE

Through the generosity and co-operation of Dr. M. H. Kniseley and his associates of the Department of Anatomy of the University of Chicago we were able to utilize a modification of the Kniseley fused quartz rod transillumination apparatus (18, 19). The main features of this apparatus are the employment of a cold light source and a constant temperature bath with variable volume flow. The apparatus was constructed essentially as shown in Figures 1, 2, and 3. A Leitz micrometer lens was installed in the microscope lens system. Young small dogs were used in all experiments and intravenous nembutal anesthesia.

A special lucite tray was constructed to hold the dog's mesentery in a nonstretched position submerged in constantly circulating mammalian Ringer's solution at body temperature. The tray as shown in Figure 4 was built with a lower compartment through which water circulated. This lower layer served to disperse the quartz light after it emerged from the end of the quartz rod in order to do away with the theoretical consideration that even cold light will produce warmth at the point of contact with the tissue.

From the Department of Surgery, Northwestern University Medical School, Chicago.

The microscope was fixed on small vessels in the mesentery a small vein and artery run side by side as a rule. Such a field gave us a very satisfactory view of both the arterial and venous responses. Precapillary vessels the artery measuring from .054 to .144 millimeter the vein from .090 to .288 millimeter were chosen rather than the more minute vessels or capillaries since more accurate changes in caliber could be measured at 48 diameters. The capillary bed varies from one field to another such an extent that the information derived from viewing capillary vessels alone is not always pertinent. Furthermore the reaction of the capillaries does not always parallel that of the slightly larger vessels.

Six control animals allowed to remain in the apparatus for from 4 to 8 hours showed no appreciable changes in caliber in the observed vessels. Thus any marked changes which occurred in subsequent experimental animals were considered dependable as a response to the lesion produced.

VENOUS OCCLUSIONS

In 40 animals the superior mesenteric vein was clamped with a rubber tipped artery forceps for periods ranging from 20 minutes to 2 hours 29 minutes. In order to obviate the possibility that the superior mesenteric artery might be stimulated into spasm by operative trauma the procedure was carried out in the following manner. The vein was carefully isolated and a loop of stout string placed loosely about it. The intestines were then returned to the abdomen and the abdominal wall closed temporarily by clamps. The animal was allowed to remain in this condition for periods up to an hour. The mesentery was then gently placed on the lucite tray and submerged in Ringer's solution. A control series of readings was taken to make sure that no undue changes in caliber resulted from the operative manipulation. The loop placed about the superior mesenteric vein was then drawn up and a rubber tipped artery forceps placed on the vessel. It was allowed to remain in place for varying periods of time while measurements were made on the vessels in the microscopic field. The clamp could be removed without reopening the abdomen.

The pattern of response in the observed vessels was remarkably uniform. In each of the few instances of failure to observe the usual responses the failure was due either to an overzealous dissection of the vessel from its fatty bed or to the presence of one or more accessory vessels which carried enough blood to make the occlusion incomplete. Upon ligation of these vessels the occlusion of the main stem produced the same responses in the smaller vessels as were seen in all other animals.

Following venous occlusion there was invariably a marked spasm (decrease in caliber) of the small artery and a gradual dilatation of the concomitant vein. In some instances of venous occlusion the artery diminished to $\frac{1}{2}$ its original caliber. In 7 dogs the clamp was allowed to remain in place until death of the animal. Most of these animals died in shock within 3 hours. Plasma and blood loss from the mesenteric and intestinal vessels is responsible for this shock. In 33 dogs the clamp was released after a period of occlusion, and measurements were made up to 2 hours following release.

In the animals with venous occlusion persisting until death the artery after a period of marked spasm sometimes relaxed slightly just before death, other times a state of spasm persisted. The latter usually occurred when a thrombus formed in the artery. However only rarely did this terminal loss of tone result in a diameter as large as the control. In other words the arteries were still slightly narrower than the preocclusion caliber during shock and at the time of death despite slight secondary relaxation. The concomitant vein after a period of dilatation usually became slightly narrower just before death. Occasionally it became even narrower than the preocclusion caliber.

Usually within 30 minutes of a venous occlusion the flow of blood in the vein slowed down until the stream was barely moving. At this stage there was still a rather rapid flow in the spastic artery. Groups of cells within the

It is known that the sympathetic nerves of the mesentery follow the course of the main blood vessels. Therefore, stripping the main stem mesenteric vessel of nerves eradicates sympathetic responses in the mesenteric vascular tree. It is extremely unlikely, however, that the sympathetic nerves reach the small segmental mesenteric vessels. Sympathetic denervation as incomplete procedure

artery were seen to agglutinate and travel in clumps. In a few instances the artery narrowed down to allow only a single file of cells through it. In such cases the clumps usually traveled in spurts being caught momentarily here and there on the wall of the artery. We were impressed with the possibility that such clumps can conceivably be the source of local propagating thrombi or distant emboli. The early stage of such clumping has been termed "sludge" by Kniseley (20). Kniseley and co-workers found that sludge forms in many diseases as well as in traumatic shock. Because the venous stream is so slow at this stage the clumping within the vein cannot be recognized as readily, but just before the venous flow ceases it becomes quite apparent from the irregular outline of the slowly moving stream that agglutination has occurred. At first this is only a microscopic agglutination, since cutting such a vein at this time will result in the free flow of blood from the lumen.

The behavior of the capillaries during venous occlusion does not necessarily follow

that of the vessels described above. Almost immediately after the vein is occluded the capillaries become greatly dilated. Within 5 to 10 minutes of a venous occlusion of the mesentery small ecchymotic hemorrhages occur due to overstretching and rupture of the capillary walls. This reaction of the capillaries to venous occlusion is by no means uniform. Some fields of the same mesentery exhibit such marked constriction that the capillaries are almost indiscernible. Sludge forms in the capillaries within a few minutes after venous occlusion. The difference in reaction between the precapillary vessels and the capillaries agrees with the observations of several other investigators made during experiments with widely divergent purposes (21).

After the clamp is removed from the main vein the small arteries remain in a spastic condition for varying periods of time. This residual spasm following the release of a venous occlusion apparently plays an important role in the question of viability in strangulated intestine (23). The duration of the

arterial vasospasm following venous occlusion varies considerably from one animal to another but apparently has some relation to the duration of the original occlusion. For example in one animal (Dog No. 9) with a venous occlusion of 20 minutes the artery regained its original caliber 15 minutes after the clamp was released. In another animal (Dog No. 14) with a venous occlusion lasting 27 minutes the residual spasm persisted for 25 minutes. In another instance (Dog No. 11) the ligation lasted for 1 hour and residual spasm in the small arteries was present until the death of the animal almost 2 hours after release of the clamp. Although in an occasional animal the residual arteriospasm was very short lived and bore little relation to the duration of the occlusion there was some residual vasospasm in every instance of complete occlusion.

The pattern of behavior of the smaller radicals following venous main-stem occlusion can be summarized as a moderate dilatation of the veins and marked spasm of the arteries. Following release of the occlusion the vein soon returns to its normal caliber while the artery persists in a state of residual vasospasm for varying periods of time. The capillary vessels do not follow the pattern of the precapillary artery or the postcapillary vein. Capillary behavior in general following venous occlusion is one of marked dilatation but certain areas of the capillary bed are in marked spasm at the same time.

ARTERIAL OCCLUSIONS

The same technique was used for occlusion of the superior mesenteric artery in 21 dogs as was used in the case of the vein. The clamp was allowed to remain on the artery for periods ranging from 5 minutes to 2 hours.

The pattern of response of the observed vessels was again rather constant. The difference between animals was only one of degree. In each instance the small arteries responded by a marked spasm. In most animals the concomitant vein also went into a moderate degree of spasm following arterial occlusion. The gut became very white contracted and exhibited the typical nipped appearance of superior mesenteric artery occlusion.

Upon release of the clamp from the artery the bowel flushed with reactive hyperemia. The interesting feature of this period of reactive hyperemia is that the small artery under observation maintained a definite degree of residual spasm while the capillaries became markedly dilated. This was a disturbing observation since all previous studies (12-30) on reactive hyperemia employing such indirect measurements as blood flow temperature etc. indicate that the flow during reactive hyperemia is increased. Since most studies on reactive hyperemia (12) were carried out with short term (5 and 10 minute) occlusions we ran a series of 7 short term occlusions. Our findings were no different than in the longer periods of ischemia. The small arteries maintained a definite state of spasm in the face of gross flushing of the tissues upon

Fig. 3. View of complete setup with camera in place for taking photomicrographs or motion pictures.

release of the occlusion in all but 1 instance. In this 1 case the caliber of the artery reached the preocclusion caliber but did not exceed this diameter at any time during reactive hyperemia.

Following arterial occlusion the blood in the artery slows markedly and stops within about 10 minutes. The blood in the vein runs a rather parallel course. Clumping of cells within the vessels occurs as the stream slows down in both the narrowed artery and the narrowed vein. Thus we observed the mechanism of segmental venous thrombosis in arterial occlusions.

Upon release of the clamp the artery does not usually regain its original caliber for a considerable period of time. For example, when the superior mesenteric artery was clamped for 1 hour (Dog No. 22) the residual arterial spasm following the release of the clamp lasted until the death of the animal 1 hour and 30 minutes later. However, the same relationship between the duration of occlusion and residual vasospasm does not seem to hold as it does in most cases of venous occlusion. Thus in another case of arterial occlusion (Dog No. 23) the artery was

clamped for 1 hour and 10 minutes, but it regained its original caliber within 15 minutes after release of the clamp. An interesting observation was the fact that in some instances of long term arterial occlusion the dogs died in a state of shock within 3 hours after the release of the arterial occlusion and the maintenance of spasm may have been an expression of shock in such cases. There was an obvious loss of blood and plasma through the capillary walls sufficient to account for shock.

In summarizing the pattern of behavior of the smaller vessels following arterial occlusion it can be said that both the artery and vein respond by a marked degree of spasm. The reactive hyperemia following release of an arterial occlusion is not reflected in the caliber of the small arteries. On the contrary, the small arteries may actually be in a state of spasm while the tissues grossly are more red than normal. This would indicate that the increased blood flow in the larger vessels, as reported by others and the dilatation of the capillaries during the period of reactive hyperemia are compensated for in part by spasm in the precapillary arterial bed. This is apparently protective in nature. Abramson has termed

Fig. 4 a, also Detail of double layer lucite tray. Upper lumina holds mesentery submerged in circulating mammalian Ringer solution. Thermometer indicates temperature of Ringer solution. the arterioles, the stopcocks of the capillary vessel. Thus large vessels, small vessels and capillaries may each behave differently in response to a given lesion.

STRANGULATION OCCLUSIONS

Having established a fairly definite pattern of response in the small vessels following main stem vascular occlusions in the mesenteric vessels, we were interested in whether the more peripheral occlusions, such as occurred in strangulations would give similar responses. Consequently in 12 dogs venous type strangulations were made with blinding tape involving an intestinal loop of sufficient length to give us a satisfactory microscopic view of the involved portion of the mesentery. This was usually some 15 or 18 inches of bowel. Because of the very nature of this type of occlusion it was not possible to duplicate exactly the same lesion in each animal. Nonetheless, our findings were rather constant.

Vasospasm distal to the occlusion followed most strangulations but differed somewhat in character from that following main stem occlusions. In the strangulations vasospasm was not as severe and developed more slowly while thrombosis developed more rapidly than in the main-stem occlusions. The thrombosis usually followed very closely the first signs of vasospasm. In 3 instances thrombosis actually occurred in some vessels before spasm became evident in others. In such cases the larger patent vessels decreased in caliber

Fig. 4 b.

Upon release of the strangulation residual vasospasm was observed in the still patent small arteries. Once thrombosis of a vessel was complete the vessel reacted no longer whether the bowel regained viability or not.

DISCUSSION

In measuring the responses of small vessels to occlusive lesions by means of direct micrometry, we have uncovered certain behavior patterns which until now have not been measured by direct observation. Certain features, however, have been known for some time. For example, arterial vasospasm following venous occlusion was first reported in a clinical study by Trémolières and Vêran in 1929, in which these authors described a case of arterial obliteration in the leg occurring in the course of thrombophlebitis. Following this report a number of similar articles appeared in the French (4, 5, 6, 13, 15, 16, 40), Italian (39, 44) and German (24, 25) literature. In some instances of thrombophlebitis the vasospasm was so marked that the condition was originally considered to be one of arterial embolism and actual gangrene has been known to occur (7, 42). However, the mechanism was not well understood. In 1934,

Fig. 5 Venous occlusion. A Control appearance of vein (left) and artery. B After 45 minutes venous main-stem occlusion, artery is narrower and vein is wider than control. Note petechiae from capillary in upper portion of photograph. Magnification $\times 25$.

Lanche and Kunlin (28) postulated the existence of an inflammatory exudate about the area of thrombophlebitis which they claimed threw the adjacent artery into contraction, and this in turn set up a peripheral vasoconstriction. The process was clarified by the experimental work of DeBakey, Burch and Ochsner reported in 1930. These authors found that chemical femoriliac thrombophlebitis produced a marked diminution in the volume of peripheral pulsations in the dog.

Interruption of the nerve pathways by lumbar sympathectomy abolished this effect. This indicated that vasoconstrictor impulses arose in the thrombotic vein and were transmitted to the arteries by way of the ganglia. These authors also demonstrated a diminution in pulsations following simple ligation of the main vein, making it unnecessary to implicate an inflammatory exudate as the irritant in the acute stage. By injecting irritating chemicals about the artery, they showed that the same

pattern of vasospastic responses occurred. Though the degree of spasm was not always the same, the pattern was fairly constant.

On this basis, it may be possible to explain the inconsistent clinical reports regarding the temperature of an extremity following venous thrombosis (1). If the occlusion in the main stem vein is complete from the beginning, the arterial spasm will be severe and the limb will be cold. If the thrombosis occurs in a section of the vessel allowing for partial venous circulation, the arterial spasm may be incomplete or absent, in which case the limb will be warm. Such a limb may be even warmer

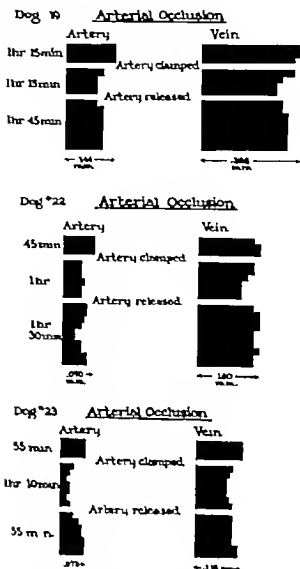

Fig. 9. Graphs showing typical patterns of behavior of small arteries and veins in main-stem arterial occlusion. During arterial occlusion there is spasm of the artery and vein with residual spasm following release of the occlusion even in the presence of gross reactive hyperemia.

than normal since there is no diminution in the arterial inflow and a partial obstruction to the outflow. Thus, as far as we can postulate from our experiments, one of the crucial issues is the position of the occlusion in the vessel in relation to accessory branches.

We found further that capillary responses do not necessarily parallel those of the artery or vein. The small artery remains in a state of spasm long after the capillaries have become widely dilated. In venous occlusions the capillaries are dilated by distention, though not uniformly so. In arterial occlusions the capillaries contract severely but eventually relax due to anoxia. Even after this type of relaxation the small arteries remain spastic.

Spasm of the small branches of an occluded artery has been described many times in the literature (8 11 31 32 35 41). Our observations not only confirmed the clinical findings reported by others but we found that residual spasm occurs in the small arteries in the presence of reactive hyperemia. Our explanation as stated rests on the fact that there is a difference in response under certain circumstances by each of the three portions of the vascular tree—the main stem the small vessel and the capillary.

Observations of the intravascular blood during the various stages of arterial occlusion have brought up certain speculations regarding the associated phenomena in clinical occlusive arterial disease. We have observed that venous spasm invariably accompanies arterial spasm in arterial occlusion. The streams in both the arterial and venous systems become retarded. Clump formation or the agglutination of erythrocytes occurs in both the arteries and veins. It would seem that here is an explanation for the thrombotic phenomenon so often seen in the venous system accompanying arterial occlusive disease. The segmental type of venous thrombosis which often is an integral part of Buerger's disease could thus be explained on the basis of clump formation in the smaller radicles of any given venous segment propagating to build a large thrombus which finally occludes the regional segment of a large vein.

In venous type strangulation occlusions we found that thrombosis played a more important role than in the main stem vascular occlusions. Spasm of the small artery occurred as it did in the main-stem occlusions, but when the small vessel became occluded by a thrombus it no longer reacted. Residual spasm was observed upon release of the strangulation as previously reported (23). When thrombosis occurred during residual spasm the spasm remained whether the bowel regained viability or not.

We are now conducting experiments utilizing various therapeutic agents such as sympathetic nerve section and certain drugs in an attempt to observe directly the effects of such agents on the caliber of the small vessels and the state of the blood in the various stages

of occlusive lesions. These findings will be reported in another communication.

CONCLUSIONS

1. Vasospasm generally accompanies main-stem vascular occlusions.
2. In venous occlusion there is a marked arterial spasm (decreased caliber) and a venous dilatation (increased caliber).
3. Following release of venous occlusions the artery remains in a state of moderate spasm for a considerable period of time. We have termed this phenomenon *residual spasm*.
4. In arterial occlusion there is a marked arterial spasm and a concomitant venous spasm.
5. Following release of arterial occlusions, grossly visible reactive hyperemia occurs but during this state the precapillary artery remains in spasm.
6. Sludge formation (Kniseley) is seen in the smaller vessels during both arterial and venous occlusions. Minute thrombi form easily in the spastic vein during arterial occlusion and may propagate thus accounting for segmental venous thrombosis in arterial occlusive disease. This observation makes it unnecessary to postulate the presence of per-arterial inflammation as a venous irritant in the production of venous thrombosis.
7. Reactivity in a small vessel becomes arrested once the vessel is thrombosed.
8. The importance of vasospasm in the phenomena accompanying vascular occlusions in general is emphasized.

III USE OF THE MOE PLATE IN THE TREATMENT OF INTERTROCHANTERIC FRACTURES

TIMOTHY A LAMPIER, M.D. ARTHUR W TROTT M.D. and
JOSEPH H SHORTELL M.D. Boston Massachusetts

Open reduction with internal fixation of intertrochanteric fractures of the femur has become an accepted procedure only within the past few years. As a rule this type of fracture will readily respond to so-called conservative meth-

ods of treatment. There is however a definite indication of these fractures in elderly patients who are poor medical and surgical risks. This fact has tended to be overlooked in the large amount of literature occasioned by the use of the Smith-Petersen triflanged nail for fractures of the neck of the femur. It is the purpose of this paper to present the use of a new type of internal fixation apparatus called the Moe plate. This plate was devised by Dr. John H. Moe of Minneapolis and to the best of our knowledge has not previously been described in the literature. During the past year the Moe plate has been used in the treatment of intertrochanteric fractures at the Boston City Hospital. Because of the highly satisfactory results obtained in this series of cases the following report is submitted.

In the past many methods of immobilization have been used to treat intertrochanteric fractures of the femur. These include abduction spica casts, well leg traction, Russell's traction, the Hodgen splint, just to mention a few. But it has been pointed out by several (1, 8, 13, 22, 25, 26) that the complications which arise out of such treatment greatly increase morbidity and mortality in the aged. It is for these reasons that open reduction and internal fixation have been advocated for the treatment of this type of fracture (6, 9, 13, 22).

In favor of the operative therapy for intertrochanteric fractures it has been pointed out that the incidence of these fractures is high, varying from 47.8 (25) to 64 per cent (24) of hip fractures, and Morris found them to be four times as frequent as fractures of the femoral neck. Thus these fractures account for a

considerable number of all hip fractures and are a serious problem in the older age groups. In addition, in older age groups intertrochanteric fractures occur more often than those of the femoral neck. In several series (2, 10, 13, 14, 16, 17, 21, 23, 26) reported in the literature the average age of patients with intertrochanteric fractures is 70.39 years, whereas that of patients with femoral neck fractures is 65.1 years (13, 26).

Other factors which contribute to the greater severity of intertrochanteric fractures are the greater trauma usually responsible for this type of fracture, with a greater degree of shock, more hemorrhage, and more soft tissue damage than that which occurs with fractures of the femoral neck. As a result there is usually more severe pain and a greater deformity. Another factor which contributes to the greater shock and pain is the marked degree of comminution of fragments which often occurs in intertrochanteric fractures. This comminution as seen at the time of operation is frequently much greater than is apparent by x-ray examination.

Most of the conservative methods of treatment require prolonged periods of immobilization and bed rest. Such procedures involve a high incidence of hypostatic pneumonia, decubitus ulcers, joint stiffness, incontinence, mental deterioration, thrombophlebitis, muscular wasting, and general debility. Early ambulation, especially of the aged, is currently much emphasized. Additionally there is a shortage of trained nurses. Hence a method by which nursing care can be reduced to a minimum and aged patients can be made ambulatory on crutches at an early period in their illness is much to be desired. This can be accomplished by open reduction and internal fixation of these fractures.

It has been shown (6, 9, 21, 22) that open reduction leads to freedom from pain almost

immediately after operation. Early crutch ambulation is possible; the patient is allowed more freedom in bed and there is a reduction in the total amount of hospitalization. Joint stiffness, limb atrophy, and bed sores are minimal or absent. Chiefly there is a decrease in mortality and morbidity. In the past 8 years several methods of internal fixation for intertrochanteric fractures have been reported (3, 6, 7, 8, 9, 10, 11, 13, 15, 16, 17, 18, 20, 22, 25, 27, 28) all with similar results in general and it is beyond the scope of this paper to report these methods.

In order to maintain reduction of an intertrochanteric fracture it is necessary to immobilize not only the fracture site but also the proximal and distal fragments. Because the neck of the femur makes an average angle of 127 degrees with the shaft, any form of fixation which transfixes only the fracture site is not sufficient in most cases to overcome the muscle pull and prevent a coxa vara deformity. This difficulty is met in most devices by a plate which attaches to the upper end of the femoral shaft. It is incorporated into the mechanism immobilizing the fracture site so as to counteract the muscle pull and to prevent the deformity. In some devices this is accomplished by a single piece (3, 8, 11, 15, 16, 17) in others by a combination of devices (7, 9, 18, 22, 25, 27, 28). The Moe plate, which is the subject of this report, is a single plate bent to fit over the greater trochanter in its proximal portion and prolonged into a plate to fit the femoral shaft in its distal portion (Fig. 1).

The Moe plate is constructed of stainless steel of the SMO 18-8 group and has the shape of a question mark; the curved portion being that portion which is molded to fit over the greater trochanter. The plate has been placed against the femur in several skeletons and has been found to fit without any change being necessary. The size of the plate is determined largely by the straight prolongation which fits over the shaft of the femur and which is drilled to accommodate from 3 to 5 screws. Before operation the size of the plate to be used can be gauged roughly by placing it against the x-ray film with due allowance for distortion and this method has been found

Fig. 1. The Moe plate.

to be quite satisfactory as the distortion encountered is seldom great enough to cause difficulty.

The curved portion of the Moe plate forms the arc of a circle with a radius of approximately 4.5 centimeters. As shown in Figure 1, it is perforated by three screw holes placed 2 centimeters apart. These holes are counter sunk for the head of the Venable wood type hip screws which are used for this portion of the plate. Thus allowance also is made for slight variations in the angle at which the screws are inserted depending upon the conditions encountered at operation. At first glance one would think that the three screws which are inserted across the fracture site and into the cancellous bone of the head and neck of the femur would abut against one another but in actual practice this problem is seldom encountered. If encountered it is easily remedied by altering the angle of insertion of the offending screw. In addition the use of the three large screws provides fixation across the fracture site in three planes and prevents deformity due to rotation besides adequately maintaining reduction.

The straight prolongation of the Moe plate has a varying number of holes as previously mentioned. Stainless steel screws of the Sher

Figs. 4 and 5. Postoperative results. Because of severe comminution, third hip screw could not be used. A slight degree of varus deformity is apparent by x-ray examination.

man type are used usually to apply this portion of the plate in the usual manner. One thing that has been noted in this study is that the first or upper hole of the plate portion lies opposite the lesser trochanter and for this reason a longer screw is necessary here than for the rest of the shaft. It is to be emphasized that the screws used should be of the S M O 18-8 group of stainless steel in order to avoid electrolytic osteitis.

Upon admission to the hospital, and after roentgenograms have been taken to determine the type of fracture the patient is placed in traction to minimize pain and shock. If operation is contemplated simple Buck's extension or Russell's traction is usually sufficient. The type of preparation depends upon the preference of the surgeon, some preferring a skin preparation of 2 days, others of 1 day.

The optimum time of operation following injury is controversial. There are some operators (8-9-25) who believe that these patients should be treated as emergency cases. Other surgeons (14-27) believe that operation should not be undertaken for 3 to 4 days during which time it can be determined whether or not the patient will survive the initial shock. In the 30 cases presented in this report the latter method of treatment was used. It is the opinion of the authors that these pa-

tients should be operated upon as soon as possible after the initial shock has been combated by the usual methods. Preoperative care should be directed toward improving the general health of the patient.

In the operating room the patient is prepared and draped in the usual manner with the involved extremity draped free. Again, the type of incision used depends upon the surgeon's preference. The two types used in this series were the straight lateral incision, and later the inverted J shaped incision (Watson Jones) as the latter was felt to provide a greater and easier exposure in the trochanteric region. The incision is made through the deeper layers through the tensor fascia femoris and vastus lateralis muscles to bone. The periosteum is incised and elevated only enough to accommodate the plate. The exposure is made adequate to visualize the fracture line in order to aid in the reduction. If the exposure is carried too far posteriorly below the greater trochanter troublesome bleeding may be encountered from large tributaries of the deep branch of the medial circumflex femoral artery.

When the exposure is adequate the fracture is reduced by traction and manipulation. If the fracture line is exposed the accuracy of reduction can be checked visually. If desired,

Fig. 6

Fig. 7

Fig. 8

Figs. 6, 7 and 8 Postoperative x ray films of Moe plating with either the 2 or 3 hip screw method.

it may be verified by x ray examination. One of the features of the Moe plate is that it may be applied without x ray control which decreases the operating time considerably. In all the cases in this series operation was carried out without x ray control but in the hands of inexperienced operators the use of x ray control is desirable. While the majority of intertrochanteric fractures are reduced by traction and internal rotation combined with abduction it was noted that several in this series required external rotation in order to effect reduction. That this was the case could not be determined from the preoperative roentgenograms.

While the reduction is maintained by an assistant or by mechanical means the plate is placed against the shaft and greater trochanter and as the fit is usually satisfactory further shaping of the Moe plate is not necessary. The outer cortex of the greater trochanter is penetrated with a large size drill point in order to allow for easier introduction of the large venable hip screws. These screws are furnished in several sizes and their length is determined roughly by comparison with the preoperative x ray films. The direction of the screw is determined by the angle of the femoral neck upon the shaft and can be gauged by a probe or clamp inserted over the anterior surface of the capsule. One of the large screws usually the longest of the three is then inserted in the middle or lower hole of the curved portion. Following this the plate is fixed to

the shaft with a screw through the first hole of the straight portion of the plate. This prevents rotation of the plate while the remaining screws are placed and also fixes the fracture. The remaining screws are then inserted. X ray examination will disclose whether or not the large screws are too long. If any screws project into the acetabulum they should be removed and replaced by shorter ones.

In the markedly comminuted type of intertrochanteric fracture it is not always possible to align all the small fragments but the major fragments can be held without difficulty by the Moe plate as illustrated in Figure 2. It is in these comminuted fractures which cannot be held with other devices that the Moe plate shows its greatest usefulness. In several of the cases in this series the original plan was to use a different fixation device but because of the comminution the Moe plate was the only de-

Fig. 9. Coxa vara deformity

vise that could be used. The cortex in this type of fracture is usually too fragmented to use nails and single large elements and the lines of fracture too diverse for other devices to hold. The Moe plate however can be applied and used to maintain the reduction as the curved element depends for its holding power on the grip of the screws in the cancellous bone of the neck and head of the femur proximal to the fracture site. In the presence of marked comminution it is not always possible to use three large Venable hip screws especially at the uppermost screw hole. In these cases with the use of a special washer provided with the plate a Sherman type screw can be used to aid in the fixation. In instances where there are complicating subcapitellar fractures in addition to comminution in the trochanteric region use of the Moe plate was not attempted as osteotomy offers the only solution as a rule.

After the plate is applied the solidity of fixation can be tested by moving the hip. The femur will move as one piece if reduction is maintained. The wound is then closed in layers and a dressing applied.

The after care is the same as for any open reduction of hip fractures. It was found that the use of Buck's extension with 5 to 10 pounds traction for 2 to 3 days postoperatively reduced the degree of postoperative pain probably due to the relief of muscle spasm. The patients are made ambulatory on crutches as soon as possible after operation usually after learning to get along in a walker first. The time at which patients can be made ambulatory on crutches depends upon the individual's ability and co-operation provided the patient's general condition does not preclude ambulation. Crutches are used until roentgenograms show that union has taken place usually in 10 to 16 weeks.

The chief difficulty with either conservative measures or internal fixation including the Moe plate is the frequent coxa vara deformities which may result from too early weight bearing inadequate reduction or the tendency of patients to bear weight too early in spite of instructions to the contrary (Fig 9).

This report is concerned with the presentation of 30 unselected cases of intertrochanteric

fractures of the femur which were treated by open reduction and the use of the Moe plate. The patients were treated on the orthopedic and general surgical wards of the Boston City Hospital during the period from July 1 1946 to August 30 1947. This figure does not represent the total number for that period but only those for which there is sufficient data and follow up from which conclusions can be formed. The operations were performed by the resident staff and visiting surgeons on those services.

The majority of the 30 patients were charity cases and therefore came from a social status in which poor general health and nutrition was the rule rather than the exception. Consequently the mortality rate in the past has been rather high about 34 per cent (5). In this series there were 5 postoperative deaths or a mortality rate of 16.67 per cent a figure which is comparable to that of other reported series of operative cases. These deaths will be taken up in more detail later.

The average age of the patients in this series was 66.7 years which is slightly lower than that of other reported series. This may be explained in part by the fact that in the city of Boston in the majority of accident cases the patients are brought to the Boston City Hospital regardless of whether they are residents or not and a large percentage of the total seem to be in the younger age groups.

The mode of accident was usually the same in all cases of this series namely a slip and a fall either in the home or on the street. The preoperative methods of traction used were varied depending upon the surgeon's or resident's preference. Fourteen patients were treated with Russell's traction preoperatively 9 by simple Buck's extension 3 with balanced suspension traction and skeletal traction through the proximal tibia and 1 first by Buck's and then by Russell's traction. In 3 cases the method used is unknown. The use of traction in this series preoperatively was to alleviate pain and help to make the patient more comfortable.

The interval between the day of admission and the day of operation varied considerably—from 3 days to a maximum of 51 days. The average interval was 12.8 days. The discrep-

ancy between minimum and maximum interval may be accounted for by the fact that operation was performed as soon as possible after admission on the orthopedic service with the 3 day interval being considered necessary at the time to allow the patient to recover from the initial shock and trauma. On the other hand, on the general surgical services operation was usually delayed for one reason or another. In addition several patients on the general surgical services who after conservative treatment showed marked deterioration after 3 to 4 weeks were transferred to the orthopedic service for operation. These were cases in which the illness threatened to be terminal if the patient did not soon become ambulatory. As a result operation was carried out at a late date on several patients as a life saving measure which was not always successful. In 6 of these cases so transferred the reason was given as general debility and decubitus ulcers and the interval between admission and operation in these cases was 31, 24, 51, 23, and 24 days respectively.

It is interesting to note the number of hospital days required for this series of patients was 51, 6 days. This is longer than is reported by Morris whose patients had an average hospitalization of 29.5 days and of Harmon whose patients averaged 40 days but it is less than that reported for patients treated by traction (16, 24) and less than the average of 62.3 days reported by Johnson for the hanging cast therapy. Part of the length of hospitalization in this series is due to the long interval between admission and operation as explained in a previous paragraph. Another factor which contributed to the prolonged hospitalization was the fact that a number of the patients were destitute and had to be kept in the hospital until the social service department could arrange for placement in a convalescent home or chronic care hospital. This protracted care tended to elevate the general average as 2 cases of this sort were hospitalized for 114 and 112 days respectively. The shortest hospitalization was 21 days which occurred with 3 patients. As reported by Leydig and Brookes the average hospital stay for intertrochanteric fractures was 84.7 days for charity patients

and 56.4 days for private patients. This is an important and pertinent comparison when total hospitalization is discussed, although their series consisted of nonoperative cases. Lucas and Varney reported an average hospitalization of 45 days for operative cases, although Morris' figure for total hospitalization was low. He believed that this figure was increased because many of his patients had inadequate facilities for home care. We believe that in the absence of social service problems it is reasonable to assume that operative treatment will greatly reduce the number of hospital days required for the treatment of this type of fracture.

In any series of operative cases the presence or absence of sepsis should be noted. In our series there was 1 case of a superficial wound infection which responded to local therapy and might well have been due to the handling of the wound beneath the dressing by the patient. Many of the patients received penicillin as a postoperative routine and this may have been a factor in the low incidence of wound infection.

As would be expected in any series which deals with the older age groups, there were several other complications which should be noted. Bronchopneumonia occurred in 5 cases after operation but this disease was nonfatal in all and responded well to treatment. In 3 cases a low-grade fever occurred postoperatively for several days for which no adequate explanation could be found. As most of the patients in this series were checked routinely each day for evidence of thrombophlebitis and phlebothrombosis this mechanism as a cause of the fever can probably be eliminated. Cardiac decompensation occurred in 1 patient after operation. Superficial phlebitis in another and 1 patient had persistent ankle edema of the affected limb following surgery.

Table I summarizes other aspects which were considered in this series. We set up a rather arbitrary classification for these cases before and after operation. Those classified as good include the patients who had no complicating injuries or medical diseases and who were active prior to injury. The 'fair' group includes patients with such conditions

TABLE I.—STATISTICAL BREAKDOWN 30 CASES INTERTROCHANTERIC FRACTURE

		Rarely shock*							

*One recipient shock on operating table
 †Euthy during operation or immediately postoperative

as mild or moderate cardiac decompensation secondary anemias severe arteriosclerosis general debility severe malnutrition mild hemiplegias diabetes of moderate severity moderately poor renal function etc. For those who did not fit in the above categories the classification of 'poor' was made and included patients with complicating medical conditions of a severe nature. It is the latter group that accounts for the mortality rate of 16.67 per cent which is a figure consistent with the average mortality rate of 17.09 per cent of several reported series of operative cases (9, 11, 13, 16, 17, 21, 25, 26).

Although only a little over 50 per cent of the patients in this series were treated with penicillin for 24 hours before operation we are inclined at the present time to treat all bone repairs with this drug before operation. In the only case in which superficial wound sepsis occurred, the patient received 40,000 units of penicillin every 3 hours for 1 day prior to surgery.

Transfusions of 500 cubic centimeters of whole blood were given to 15 patients either during or immediately following surgery and 1 additional patient required a total of 1,000 cubic centimeters of whole blood to combat shock. The remaining patients were given intravenous fluids during the operative procedure. At the present time, all patients unless robust are given at least 1 transfusion during the operative procedure which enables them to tolerate the surgery much better.

Technical surgical difficulties were few. Of the 30 cases only 3 patients or 10 per cent presented problems of any marked degree. In 1 case the operative procedure was difficult

because of severe comminution at the fracture site and there was some delay in securing reduction and proper alignment of the fragments. The other 2 cases were problematical as 3 or more weeks had elapsed before surgery was undertaken for reasons previously mentioned. In 1 of these a fair amount of osteoid tissue in the midst of a large hematoma was located between the fragments and this had to be evacuated before definitive surgery could be carried out. The third and last case which presented any difficulty was that of a patient who had been treated conservatively for a period of 7 weeks without the appearance of any definite callus by x ray examination. This patient was transferred from a general surgical service to the orthopedic service for surgery because of large decubitus ulcers and progressive mental and physical deterioration. In this instance when the fracture site was exposed attempts to abduct the femoral shaft were futile until the iliopsoas and adductor muscle groups were freed. Therefore, in a review of this series of cases it is apparent that the only real obstacle one may expect to meet is a difficult reduction and prolonged operating time due to comminution of the fragments. This applies only to those cases wherein surgery is performed within a few days after injury. As previously stated no technical surgical difficulties were met in applying the Moe plate once the fracture had been reduced.

In the analysis of the 5 patients who died, all were poor surgical risks. S. C. B. C. H. No. 1237213 was a 90 year old female who had been treated conservatively and had received intensive medical therapy for 16 days prior to operation. As her condition began to deterio-

TABLE II.—RESULTS OF FOLLOW UP EXAMINATIONS AT END OF 6 MONTHS

Patient	Flexion		Internal and external rotation, Hip	Ankle edema	Ambulation	Shortening, inches	X-ray examination	Pain
	Hip Degrees	Knee						
	90	45	90% normal	None	Without crutches 1 end of 3 mos.	1/4	Good callus end of postoperative week	None

rate rapidly toward the end of her second hospital week the operation was carried out as a life saving procedure. In spite of transfusions during operation and immediately after operation she lapsed into shock of an irreversible nature and died 2 hours after the operation. In this case, one might argue that it would have been better to let nature take her usual course, but as the situation of the patient was desperate it was felt justifiable to take the risk. The other 4 deaths were among patients who had poor cardiac reserve and their deaths were chiefly cardiac in etiology. M.P. B.C.H. No. 1215783, was a 64 year old female who died of a terminal cerebrovascular accident and complicating bronchopneumonia. M.F., B.C.H. No. 1228571, was a 73 year old female whose death was due to cardiac decompensation and bronchopneumonia 5 days after operation. Complicating diseases in this patient were arteriosclerotic and hypertensive heart disease and mild diabetes. L.G., B.C.H. No. 1225408 was a 75 year old female who died 23 days after operation because of cardiac decompensation and severe diabetes. C.K., B.C.H. No. 1240252, was a 75 year old female who died of cardiac decompensation and arteriosclerotic heart disease 55 days after operation with a further complication of bronchopneumonia. It is our belief that the latter 4 deaths could not have been avoided due to the patients extremely poor cardiac reserve, and that in all probability the results without surgery would have been equally disastrous.

Of the total of 30 patients only 5 (16.67%) or 20 per cent of the living were able to return to our follow up for clinical evaluation. As a last resort, questionnaires were sent to all in the hope that we might be able to appraise the end results of this method of treatment of intertrochanteric fractures. Of the total of 20 letters sent, only 11 questionnaires were filled out and returned. Four letters were 'returned to sender—address unknown,' and no reply was received from the remaining 5 patients. In other words, follow up information was obtained from only 64 per cent of those patients believed living.

Table II summarizes the results of the examination in those 5 patients who were seen in the follow up clinic. Of the 11 questionnaires received, 1 indicated that the patient had died of heart disease 10 months after discharge from the hospital. Five patients indicated that they were ambulatory without the aid of crutches and of these 4 were using canes. All 11 patients complained of mild or moderate hip pain aggravated by damp or cold weather. None was bed-ridden, but 2 patients stated they were restricted to armchairs. Six patients complained of mild or moderate stiffness of the knee joint. Seventy per cent reported mild ankle edema which subsided with bed rest and all but 1 patient claimed to have some limitation of hip flexion varying from 50 to 90 per cent. All the reports indicated that the patients were able to cross the injured leg over the uninjured member.

Because of its subjective nature information acquired through questionnaires is not generally as reliable as that acquired through physical examination. However as the patients could not, or would not report to our follow up clinic, we were forced to resort to this inferior method for evaluating the end results of this procedure. The follow up results in these cases include quite a few patients who were seen or heard from more than a year after their operation.

CONCLUSIONS

1 The Moe plate is a simple adequate and effective method of immobilization in the operative treatment of intertrochanteric fractures.

2 The application of the Moe plate creates a minimal amount of trauma due to the ease of application and the shortened operative time.

3 X ray control is not necessary but can be used if desired.

4 With this method patients can be made ambulatory on crutches shortly after operation which is an important factor to minimize complications in the older age groups in which this type of fracture most frequently takes place.

5 The mortality rate in this series of 30 cases is 16.67 per cent, which is considerably less than that for so-called conservative methods and the figure is consistent with that reported from other hospitals and clinics for surgically treated intertrochanteric fractures.

6. The Moe plate can be used very satisfactorily in the markedly comminuted intertrochanteric fractures in which it is not possible to maintain reduction with the other types of internal fixation thus far reported in the literature.

THE EFFECTS OF VARIOUS TYPES OF SYMPATHECTOMY UPON VASOPRESSOR RESPONSES IN HYPERTENSIVE PATIENTS

ROBERT W WILKINS M.D., JAMES W CULBERTSON M.D., and
REGINALD H. SMITHWICK, M.D., F.A.C.S., Boston Massachusetts

IN order to determine the effects of removing various portions of the sympathetic nervous system upon vasomotor reactions it is necessary to measure these reactions in the same individuals both before and after surgery. Thus if responses are shown to occur regularly before sympathectomy and are uniformly absent or altered afterward, one may conclude that the operation has been responsible for the change. For example, vasomotor reactions studied in the limbs by simultaneous measurements of blood flow and blood pressure have been found to be profoundly altered by sympathetic denervation of the parts (4).

In the splanchnic areas of human subjects vasomotor responses are difficult to measure. However, by continuously recording the ballistocardiogram along with the arterial pressure, it has been possible to distinguish the effects of changes in cardiac output from changes in peripheral resistance during vasopressor responses (5, 6). Thus it has been shown that certain vasomotor stimuli regularly cause reactions that can be attributed only to vasomotor activity in areas other than the limbs and brain. The present study was undertaken to determine the effects of surgical removal of various portions of the sympathetic nervous system upon the vasopressor responses of patients to standard stimuli. In this way the roles played by different parts of the sympathetic nervous system in these responses have been demonstrated.

From the Evans Memorial, Massachusetts Memorial Hospitals, and the Departments of Medicine and Surgery, Boston University School of Medicine, Boston, Massachusetts.

On this paper together with preceding work, the John Horsley Memorial prize of the Department of Medicine of the University of Virginia was awarded on April 28, 1948 to Dr. James W. Culbertson.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 9-1947.

METHODS

The subjects were patients, mainly hypertensive, selected for surgical sympathectomy of various types. They were studied before and again approximately 2 weeks after the completion of the operations. In addition certain patients were studied at longer intervals and of these some were studied only after operation.

Measurements were made with the patients lying quietly on the tilting ballistocardiograph (7). Arterial pressure was registered optically by a Hamilton manometer (1) attached to a needle in the brachial or femoral artery. Cardiac output was estimated with the ballistocardiograph (3), and respiration and expiratory pressure were recorded by suitable tambores placed in the same optical system. A number of sympathetic nervous stimuli were applied including tilting into the upright position, production of reactive hyperemia in the limbs, the Valsalva experiment, the cold test and a request to do mental arithmetic. Of these the first 3 were found to be more simple and to cause more regularly a clear-cut vasoconstrictor response. Perhaps this was due to the fact that they were all primarily blood pressure lowering procedures.

With the sudden stopping of a blood pressure lowering procedure the presence of vasoconstriction could be strikingly demonstrated by the appearance of a brief marked hypertensive overshoot that carried the arterial pressure above control levels and could not be explained by increases in cardiac output (5, 6). The stimuli were stopped suddenly as follows. The subject after standing upright for 5 minutes, was quickly tilted back into a horizontal position, similarly, after 15 seconds of reactive hyperemia (due to the release of circulatory arrest which had been in effect during the preceding 5 minute period) in three limbs, the

*In all cases the greater splanchnic nerve was resected bilaterally from the rib cage posteriorly upwards throughout almost its entire extent. The resection is common of the greater splanchnic nerves noted in the table and elsewhere.
†A right nephrectomy had been performed elsewhere 3 weeks previously for "unilateral renal disease" as reported, taken with splanchnicectomy.

circulation in them was suddenly reoccluded or after 10 seconds of the Valsalva maneuver (forceful expiration against a fixed resistance) the subject was asked to relax quickly and completely. Recording was then continued for at least 1 minute, and ample time for full re-

covery from each stimulus was allowed before applying another.

RESULTS

Responses in normally innervated subjects. Any procedure tending to lower the arterial

Chart 1. Showing the effects of being quickly tilted (vertical line) from the upright (75°) to the horizontal position upon pulse rate, and arterial pressure (Hamilton) of a hypertensive patient before (solid dots and lines) and after (circles and interrupted lines) a lumbar sympathectomy. Before operation the subject had stood 5 minutes at the tilt-back, after operation 5 minutes.

Chart 2. Showing the effects of the release (first vertical line) and reocclusion (second vertical line) of the circulation in three limbs after a preliminary 5 minutes of occlusion in a hypertensive patient before and after a total thoracic sympathectomy. Other notations as in Chart 1.

pressure evoked in normally innervated subjects a marked vasopressor response. When the stimulus was stopped the arterial pressure quickly recovered and then overshoot the control levels, often reaching alarming peaks. These overshoots of arterial pressure furnished an easy and, in a given subject, a fairly reproducible measurement of the degree of vasopressor reaction to the stimuli. For example following a quick return of the subject to the horizontal position after 5 minutes of standing the arterial pressure quickly swung up to levels considerably higher than the previous horizontal controls (Chart 1). Likewise upon reocclusion of the circulation in the limbs after 15 seconds of reactive hyperemia and an associated fall in arterial pressure there was an overshoot to levels higher than existed before the release of the cuffs (Chart 2). Finally, following the Valsalva maneuver there was a marked overshoot of arterial pressure above the control level (Chart 3), sometimes to more than 300 millimeters of mercury (Chart 6).

The characteristic overshoots of arterial pressure that occurred after stopping such stimuli in normally innervated subjects usu-

ally appeared within 5 seconds and reached a peak within 15 seconds. They then moderated and frequently disappeared within 30 seconds after the end of the stimulus although they occasionally persisted for a minute or more. No response was accepted as neurogenic in origin that was not present within 15 seconds of stopping the stimulus.

Grading vasopressor reactivity. Because of the ease and objectivity of using these overshoots of arterial pressure to measure vasopressor reactions to blood pressure lowering stimuli they were graded as negative, or grade I, II, III, or IV on the basis of their relative height. Thus, after the Valsalva stimulus rises in mean arterial pressure less than 5 per cent above the previous control levels were accepted as negative. Overshoots of 5 to 14 per cent, 15 to 24 per cent, 25 to 34 per cent, and 35 per cent or over were designated as grades I, II, III, and IV respectively. Of all

*Arithmetic mean calculated simply as one-half the sum of the systolic and diastolic pressures.

*The first fascicles in Table I applies except as noted. The exact extent of previous operations, however, has been indicated where known.

†Greater splanchnic nerve(s) left intact.

‡Intervascular section of dorsal and ventral spinal nerve roots proximal to dorsal root ganglia and excision of sympathetic chain roots, ganglia, and mixed nerves. Intervals between the operations listed were 1½ weeks between first and second, and 16 weeks between second and third.

§The three splanchnic nerves presumably were divided bilaterally below the diaphragm. No information was available as to the plexus preserved. Autotomy also was performed with the sympathetomy in two stages.

†As reported, taken with symplectomies.

the stimuli tried the Valsalva maneuver was the most useful because it was easy and quick to do and could be repeated as often as desired. Therefore it came to be the standard test in grading vasopressor reactivity. Nevertheless the other two stimuli were also applied when ever possible and responses to them were used if necessary in grading reactivity.

Effects of various types of sympathectomy
After surgical removal of various portions of the sympathetic nervous system in these subjects pressor responses to the same stimuli were frequently changed. This was evident most strikingly when there was a complete abolition or a great reduction in the overshoots that previously had occurred after stopping

Chart 3. Showing the effects of the Valsalva maneuver (10 seconds of forced expiration) in a hypertensive patient before and after a lumbodorsal sympathectomy. Other notations as in Chart 1.

Chart 4. Showing the effects of the Valsalva maneuver in a hypertensive patient before and after a supradiaphragmatic splanchnicectomy. Other notations as in Chart 3.

such stimuli. Instead of the quick swing above the control level there was now a slow recovery, often requiring 15 to 45 seconds to return to the control level (Charts 1, 2, 3, 5, 6). Thus patients previously rated as strong reactors to the stimuli became negative or low grade reactors.

Table I summarizes the results in a group of patients studied before and after or only after lumbodorsal splanchnicectomy (2). Prior to operation the responses of all except 2 of 20 patients were grade II or higher, whereas shortly (about 2 weeks) after operation with two exceptions they were all negative. Of 12 patients studied late (5 months to 9 years) after lumbodorsal sympathectomy 2 had grade II, 6 had grade I, and 4 had negative responses. Four patients who before total thoracic sympathectomy were grade III, I, II, and I reactors respectively became negative after operation (Table II) (Chart 2).

On the other hand patients with less extensive operations remained reactive to the blood pressure-lowering stimuli (Table II). After unilateral sympathectomy, whether lumbodorsal, total thoracic, or cardiac in type, definite though sometimes reduced vasopres-

or responses were observed. Bilateral cardiac (upper thoracic) sympathectomy considerably modified but did not abolish the vasopressor overshoot. Thus 2 young patients complaining of nervousness, tachycardia, and palpitation were both grade IV reactors before cardiac sympathectomy, whereas after ward they were relieved of their complaints and were only grade I and II reactors, respectively. Another patient (grade II) who for the relief of angina pectoris had a subtotal thoracic sympathectomy and greater splanchnic neurectomy on the left side and an upper thoracic sympathectomy on the right side was a grade I reactor 5 weeks after the last operation. (The second of his 3 operations listed in Table II was done in an effort to relieve persistent thoracic pain.) A fourth patient, who had had a left total thoracic sympathectomy and a right lumbodorsal splanchnicectomy because of angina pectoris associated with hypertension, presented the interesting finding of grade II reactivity 1 3/4 years postoperatively (Table II).

In one young male ("Dun") who wished to avoid any possibility of sterility a supradiaphragmatic splanchnicectomy was performed,

*Remaining portions of the greater splanchnic nerves were removed entirely whenever possible. The exact extent of previous operations elsewhere has been indicated when known. Numbers designating sympathetic ganglia and segments of trunks named are inclusive. The first five patients are listed also in Table II, and patients "Als" and "Kat" also in Table I.

†As far as the splanchnic nerves were removed above the diaphragm on both sides as well as corresponding portions of the sympathetic trunk. ‡Small resect, splanchnic sympathetomy with only thoracolumbar chain ganglia below L₄ or L₅ remaining. §Transverse section of the thoracic segment of the third lateral thoracic nerve was also performed bilaterally. The final surgical result was as reported, taken with epinephrine-sympathetomy.

leaving the lumbar ganglia intact. He was a grade IV reactor before surgery with a 50 per cent overshoot of the mean arterial pressure after the Valsalva test and following operation he was still grade IV with a 40 per cent overshoot (Table II) (Chart 4). Of 4 other patients studied 1½, 4, 4½ and 6 years, respectively after similar operations one was a grade III, two were grade II and one was a grade I reactor. The grade III reactor was reduced to grade I after unilateral and to negative after bilateral lumbodorsal extension downward (Table III). The two grade II reactors both became negative after transthoracic extension upward (Table III) (Chart 5).

Two patients who 8½ and 4½ years previously had infradiaphragmatic operations were grades II and III respectively but after a supradiaphragmatic extension in the first and a lumbodorsal extension in the second both were negative (Tables II and III) (Chart 6). Three patients who already had had subtotal sympathectomy (lumbodorsal previous-

ly followed by transthoracic extension) before they were studied were all negative reactors (Table III). Two others were grade I and negative respectively about 3 years after a previous lumbodorsal sympathectomy and both were negative 2 weeks after transthoracic extension of the sympathectomy upward.

DISCUSSION

The methods described above seem to furnish a means of assessing the relative amount of sympathetic nervous vasopressor reactivity especially in any one individual tested under different conditions as before and after sympathectomy. The Valsalva test in particular appears to be valuable clinically since the degree of overshoot following this one simple maneuver seems to be well correlated with the amount of splanchnic sympathetic innervation remaining intact, provided the cardiac acceleratory nerves have not been interrupted.

It appears that such vasopressor responses to blood-pressure lowering stimuli depend up-

Chart 5. Showing the effects of the Valsalva maneuver before and after an extension of a supradiaphragmatic splanchnicectomy to a total thoracic sympathectomy. Other notations as in Chart 3.

on the *quantity* as well as the *location* of the functioning sympathetic nervous tissue. Thus a total thoracic sympathectomy in which the lumbar ganglia are left intact is more effective in abolishing the responses than is a supra diaphragmatic splanchnicectomy or an upper thoracic sympathectomy leaving the same ganglia intact. On the other hand, an infra diaphragmatic operation removing the first and second lumbar ganglia but extending upward only to include the 12th dorsal ganglia is less effective in reducing the overshoots than is a lumbodorsal sympathectomy from the 8th dorsal through the first lumbar ganglia. However a total thoracic sympathectomy or even a "subtotal sympathectomy" (lumbodorsal plus upper thoracic denervation) is no more effective than a complete lumbodorsal operation. In fact, it is possible that total thoracic sympathectomy may appear to be more effective in abolishing purely vasoconstrictor activity than it actually is, since by preventing the cardiac acceleratory component of the vasopressor response it retards and lessens the overshoot masking any vasoconstriction that may be present. A simple cardiac denervation (i.e. a high thoracic sympathectomy) likewise minimizes the acceleratory

Chart 6. Showing the effects of the Valsalva maneuver before and after an extension of an infradiaphragmatic splanchnicectomy to a lumbodorsal splanchnicectomy. Other notations as in Chart 3.

response but also decreases both the diastolic and systolic overshoot suggesting that certain fibers concerned in the vasoconstrictor reaction may be interrupted by the operation.

From the study of cases long after operation it appears that the type and extent of the original surgical procedure are more important factors than is the elapsed time in affecting the vasopressor response found later. This indicates that after extensive operations regeneration is usually slight, a most important fact to know whenever a poor result or a recurrence of symptoms is found after operation.

Finally, the results show that sympathetic vasopressor responses to blood-pressure lowering procedures may be superimposed upon any grade of basal arterial pressure, the height of which may bear no direct relationship to the degree of this type of activity and may or may not be changed by procedures which profound

ly alter the reflex responses. If superimposed upon a high basal level of arterial pressure such reactions may result in dangerously high peaks during which vascular rupture or other types of damage may occur. In such cases it would seem wise to abolish the reflex vasopressor responses even when the basal levels of arterial pressure might not be lowered by the operation. This conclusion apparently has been justified by the more benign course of many hypertensive patients after a sympathectomy which has failed to produce a significant change in the basal arterial pressure.

SUMMARY AND CONCLUSIONS

1. Overshoots of arterial pressure appearing quickly after the cessation of blood-pressure-lowering procedures furnish a means of grading the amount of sympathetic nervous vasopressor reactivity of human subjects.

2. The grade of vasopressor reactivity of a subject is markedly decreased or abolished

after extensive bilateral sympathectomy. It is less affected by less extensive sympathetic denervations.

3. The grade of vasopressor reactivity is not necessarily related to the resting level of arterial pressure of a subject.

4. The abolition of overshoots of arterial pressure in hypertensive patients appears highly desirable.

FECAL CONTINENCE FOLLOWING RESECTIONS OF VARIOUS PORTIONS OF THE RECTUM WITH PRESERVATION OF THE ANAL SPHINCTERS

EUGENE A. GASTON M D F.A.C.S., Framingham, Massachusetts

IN a previous communication studies on the physiology of fecal continence in normal individuals were presented (2). The purpose of this paper is to present similar studies of 4 patients in whom the anal sphincters have been retained following resections of various portions of the sigmoid colon and rectum. Interpretation of these studies is aided by kymographic tracings of the anal reflexes obtained on stimulation of different levels of the sigmoid and rectum in normal individuals. These studies indicate that the rectum itself is an integral part of the sphincteric apparatus and that the retained sphincters are incapable of maintaining sphincteric continence if too much of the rectum is removed.

SPHINCTERIC CONTINENCE IN NORMAL INDIVIDUALS

It is of the greatest importance to understand that fecal continence may be of two types: colonic and sphincteric. Colonic continence refers to the plastic adaptation of the smooth muscle of the colon to the enlarging fecal mass; it is retained following resections of the rectum whether the sphincters are preserved or not. Thus, even in patients with abdominal colostomy in whom there is no sphincteric apparatus, attention to diet and colonic irrigations at regular intervals eventuates in a type of continence which is surprisingly satisfactory. Failure to evaluate the role played by colonic continence when the anal sphincters have been preserved following resections of the rectum may lead to erroneous conclusions as to the efficiency of the retained sphincters.

Sphincteric continence refers to the conscious and especially to the reflex retention of

bowel contents by contraction of the external sphincter muscle. The internal sphincter, which relaxes when the rectum is stimulated, appears to play no part in sphincteric continence. Since sphincteric contraction is not associated with any damping effect on colonic peristalsis (1), the closing force of the sphincter must exceed the propulsive force of the colon in order to be effective. The normal external anal sphincter has been shown to lack endurance. This lack of endurance makes necessary a mechanism whereby the sphincter may be warned as to when and to what degree its services are required. Previously reported studies of normal individuals indicate that such a mechanism exists in the form of a reflex arc. The afferent fibers of this arc arise in the wall of the rectum and communicate at cerebral levels with efferent fibers which terminate in the external anal sphincter (2).

Under normal circumstances colonic and sphincteric continence are of equal importance. Colonic continence appears to be responsible for the retention of feces over long periods of time through the plastic adaptation of the smooth muscle of the colon. When this plastic adaptation reaches an end and peristalsis begins, the fecal masses are pushed into the rectum in the wall of which afferent impulses are initiated. These afferent impulses, traveling over nervous pathways, (a) give rise to a sensation of imminent defecation located in the perineum and (b) initiate a reflex by which the external sphincter is able to contract sufficiently to resist the propulsive force of colonic peristalsis. Sphincteric resistance to colonic peristalsis is followed by further plastic adaptation of the colon and rectum and appropriate relaxation of the sphincter. Sphincteric continence is therefore an emergency mechanism which is called into play for only relatively short periods of time.

From the Department of Surgery of the Boston University School of Medicine and the Surgical Services of the Framingham Union Hospital.

This work was aided by a grant from the Lydia G. Raymond Research Fund of the Framingham Union Hospital.

Fig. a, Single obturator method of recording changes in sphincter tone that accompany stimulation of the rectum. b, Double obturator method which permits simultaneous and independent recording of the changes of tone of the internal and external sphincters.

METHODS AND MATERIAL

The anal reflexes were studied by means of the apparatus illustrated in Figures 1a and b. The rectum or colon was stimulated with a rubber balloon which was filled by increments and emptied by decrements with a syringe. Pressure changes in the balloon were recorded

kymographically. Changes in anal sphincter tone resulting from this stimulation were also recorded kymographically by means of a single (Fig. 1a) or double (Fig. 1b) obturator. The combined activities of the internal and external sphincters were recorded by placing the single obturator across the entire anal

canal. When the single obturator was pushed into the anal canal so that only its proximal half was recording, while its distal half protruded into the cavity of the rectum, changes of tone of the internal sphincter were recorded. When the single obturator was pulled partially out of the anal canal so that only its distal half was compressed it was possible to record the activity of the external sphincter. The double obturator was divided by a thin metal septum into proximal and distal compartments each of which was connected for independent kymographic recording. When the septum was placed at about the middle of the anal canal the activities of the internal and external anal sphincters were recorded simultaneously and independently.

By these methods studies were made of the anal reflexes of 12 normal individuals in whom the stimulating balloon was placed at various levels in the sigmoid and rectum. Studies were also made on 4 patients in whom the following surgical procedures had been previously carried out: (1) resection of the distal sigmoid colon and all of the rectum with anastomosis at the mucocutaneous line; (2) anterior resection of the sigmoid with anastomosis at the level of the peritoneal reflection; (3) resection of the sigmoid and upper half of the rectum with anastomosis 7 centimeters above the anus; (4) resection of the sigmoid and rectum with anastomosis 1 centimeter to 2 centimeters above the anus.

The number of surgical cases is small because the indications for sphincter preservation in the presence of malignancy have been rigidly limited to the following situations: (1) very early tumors involving one half or less of the circumference of the bowel and with the lower border of the tumor at least 6 centimeters and preferably 8 centimeters or more above the proposed site of anastomosis; (2) palliative resections done in the presence of liver metastases when the tumor lies at least 5 centimeters above the site of anastomosis.

RESULTS

A. The anal reflexes resulting from stimulation of different levels of the rectum and sigmoid in normal adults. In 12 normal adults the changes in tone of the internal and external

Fig 2. Kymographic tracings of the changes of external and internal sphincter tone in a normal adult with the stimulating balloon placed at various levels above the anus. In A, the balloon was 24 centimeters above the anus, in B, 27 centimeters above the anus and in C, 20 centimeters above the anus. Small letters of each test indicate simultaneous ordinates. Pressure scales in centimeters of water.

anal sphincters were recorded during stimulation of the sigmoid colon and rectum at various levels by means of the balloon. All such experiments gave essentially similar findings and a typical example is illustrated in Figure 2. A, B and C of Figure 2 are the results of three separate tests made in the same individual with the balloon at different levels. These and subsequent illustrations are similarly arranged so that the upper line represents the activity of the external sphincter, the middle line the internal sphincter, and the lower line the filling (upward curves) and emptying (downward curves) of the balloon by increments and decrements. In all tests illustrated in Figure 2 the increments and decrements were each 50 cubic centimeters. Simultaneous ordinates on the three graph lines of each test are indicated by small letters.

During test A the stimulating balloon was placed in the sigmoid colon 24 centimeters

above the anus. Filling the balloon with 5 increments caused no change in the tonus of either the internal or external anal sphincter. The same is true of the 5 decrements by which the balloon was emptied. In test B the balloon was placed in the upper rectum 17 centimeters above the anus. With each increment of filling of the balloon the internal sphincter tone fell for a short time after which it returned to the preinjection level. There was no change in external sphincter tone during these injections. No significant changes of either internal or external sphincter tone were recorded with the decrements of emptying. In test C the balloon was placed 10 centimeters above the anus. Each increment of filling was accompanied by a partially sustained fall of internal sphincter tone of significant degree. During the decrements of emptying of the balloon there was a considerable recovery of internal sphincter tone. At the same time that the internal sphincter tone was falling the external sphincter tone not only did not fall but, at points *a b d* and *e* showed significant elevations of a short period of time.

Figure 2 demonstrates that both the internal and external sphincter responses become more active when the stimulating balloon is placed closer to the anus. When the stimulus is applied to the sigmoid colon no reflex activity of either sphincter is recorded. When the stimulus is applied to the upper rectum the sphincter responses are present but feeble. They become progressively greater as the stimulus is applied closer to the anus. These findings indicate that the receptor units of the anal reflexes are absent in the sigmoid colon; that they are relatively sparse in the upper rectum but that they become progressively more numerous per unit area as the anus is approached. This receptor mechanism present only in the rectum is therefore the origin of afferent stimuli by means of which warning is given to the external sphincter as to when and to what degree contraction is required to maintain sphincteric continence. The consistent fall of internal sphincter tone when the rectum is stimulated illustrates again that this part of the sphincteric mechanism prepares the way for evacuation of feces and that it plays no part in sphincteric continence.

The sensations resulting from distending a balloon in various parts of the colon and rectum have been described by Hertz, and were amply confirmed in this group of normal individuals. When the balloon was placed in the sigmoid its distention caused discomfort in the lower abdomen usually in the midline but often in the left lower quadrant. Distention of the balloon when it was in the upper rectum caused a sensation in the sacral or perineal region that was interpreted as an urge to defecate. The lower in the rectum the balloon was placed the greater was the sacral or perineal sensation that resulted from an equal degree of distention. An evaluation of the sensation experienced by the patient when defecation was imminent was thus of some value in establishing the presence of functioning afferent nerve fibers arising in that portion of the rectum that had been retained.

B Loss of sphincteric continence following resection of all of the rectum. A 53 year old woman (Bramingham Union Hospital No. 72755) had an early grade 2 adenocarcinoma involving one third of the circumference of the rectum. The lower border of the tumor was 8 centimeters above the anus. Eighteen months before this study the distal half of the sigmoid and all of the rectum were resected and an anastomosis of the sigmoid colon to the anal canal at the level of the mucocutaneous line was accomplished a modification of the "pull through" technique being used. A transverse colostomy was also done. After healing was complete and the line of anastomosis had been dilated to normal size the transverse colostomy was closed.

Since recovery from the operation the patient remains able voluntarily to contract the anal sphincter with good force and healing has been so perfect that on examination, there is little to suggest that the rectum has been removed. In spite of this apparently perfect anatomical result she remains unable to retain gas and feces.

This intelligent and co-operative patient has made pertinent observations on the mechanism of the incontinence. She states that the perineal sensation which before operation indicated a desire to defecate is no longer present. When gas or feces passes through the anal canal

Fig. 3. Tracings taken from patient in whom the entire rectum was resected with anastomosis of sigmoid to anus at the mucocutaneous line. A, Single obturator across entire anal canal records two voluntary sphincter contractions.

B External sphincter tone and C, internal sphincter tone recorded simultaneously with the double obturator. D, filling A to e and emptying, f' to j of balloon placed 10 centimeters above the anus.

however, a normal sensation of evacuation is present. When the anal sensation is noted the sphincter is voluntarily contracted but not until after some gas or feces has escaped. In other words she has no knowledge of when or to what degree to contract the external sphincter until bowel content has passed beyond the point where it can be controlled by sphincteric contraction.

This analysis by the patient was confirmed by carefully observing sphincteric activity during an enema. The colon was sufficiently filled to set up peristaltic waves which were recorded kymographically, and it was shown that each elevation of pressure in the 'rectum' preceded by an appreciable period the onset of sphincteric contraction. It was repeatedly noted that sphincteric contraction did not take place until after enema fluid had escaped through the anal canal.

The effect of resection of the rectum on the anal reflexes in this patient is illustrated in Figure 3. The graph line marked 'A' was

made with the single obturator across the entire anal canal and records two voluntary sphincter contractions both of which fall well within the range of normal in both strength and duration (2). These indicate a good anatomical result. Lines 'B' and 'C' indicate respectively the activities of the external and internal sphincters as recorded with the double obturator during stimulation of the bowel by means of a balloon placed 10 centimeters above the anus. Line 'D' shows 25 cubic centimeter increments of filling (upright curves a' to e') and decrements of emptying (downward curves f' to j') of the balloon. As would be expected from the results of tests on normal individuals no reflex activity of the sphincters resulted from stimulation of that portion of the sigmoid colon which had been placed in the pelvis to replace the resected rectum and the similarity to test A in Figure 2 is evident.

During recent months this patient has been on a colostomy regimen, consisting of a constipating diet and colonic irrigations every sec

Fig. 4. Resection of sigmoid colon with anastomosis at level of peritoneal reflection. A, External sphincter and B internal sphincter recorded with the single obturator. Arrows pointing up indicate increments of filling of the balloon placed 2 centimeters above the anus. Arrows pointing

down indicate decrements of emptying of the balloon. C, External sphincter and D, internal sphincter tone recorded simultaneously with the double obturator. E, Filling and emptying of the balloon placed 2 centimeters above the anus.

and day. By this means regular bowel habits have developed to such a degree that she is rarely embarrassed. This is the same type of continence that is developed by patients with abdominal colostomy. It is colonic continence and has nothing to do with the retained anal sphincters. The retained sphincters are of no practical value and, from the standpoint of fecal continence, the patient has no more than a perineal colostomy. It is of some interest that she much prefers the present perineal opening to the abdominal colostomy which for several months she managed with equal skill. The chief reason for this preference is the greater ease and cleanliness with which colonic irriga-

tions can be evacuated through the perineal opening. The cosmetic disadvantages of the abdominal colostomy are an important secondary reason.

C Preservation of sphincteric continence following anterior resection of the sigmoid with anastomosis at the level of the peritoneal reflection. Because the anal reflexes are elicited in normal adults only on stimulation of the rectum and not on stimulation of the sigmoid colon, it might be anticipated that sphincteric continence would not be altered by anterior resection of the sigmoid with anastomosis at the level of the peritoneal reflection. That such is the case is illustrated in Figure 4. These

Fig 5 Resection of sigmoid and upper rectum with anastomosis 7 centimeters above the anus. A Before operation. External and internal sphincter tone recorded simultaneously with double obturator Balloon 10 centimeters above anus. B After operation, double obturator method. Balloon 5 centimeters above anus.

graphs were obtained from a 61 year old woman (Framingham Union Hospital No 75445) following resection of a grade 3 adenocarcinoma of the middle of a long loop of sigmoid colon. The sigmoid and its mesentery were resected and an anastomosis was completed between the descending colon and the 'rectosigmoid junction'. Following recovery the patient noted no change in her ability to retain gas or feces by sphincteric contraction and imminent defecation was associated with a normal perineal sensation.

In Figure 4 lines "A" and "B" representing respectively the activities of the external and internal sphincters were obtained with the single obturator. The balloon was placed 10 centimeters above the anus. Arrows pointing upward indicate the beginning and end of injections of 50 cubic centimeter increments into the balloon (a to e and a' to e') while arrows pointing down (f to j and f' to j') indicate the withdrawal of 50 cubic centimeters decrements. The normal contraction response of the external sphincter and the normal relaxation response of the internal sphincter are well shown. Lines "C" (external sphincter) and "D" (internal sphincter) were obtained simul-

taneously with the double obturator. Line "E" shows the filling (upward curves) and emptying (downward curves) of the balloon placed 10 centimeters above the anus. Normal reflex responses of both sphincters are again evident. These findings indicate that the rectoanal reflexes have not been altered by resection of the sigmoid colon.

D Preservation of sphincteric continence following resection of the sigmoid and upper rectum with anastomosis 7 centimeters above the anus. Since it has been shown that resection of all of the rectum causes loss of sphincteric continence while resection of the sigmoid with preservation of the rectum does not alter sphincteric continence the question arises as to how much rectum must be retained, along with the sphincters to conserve sphincteric continence. That sphincteric continence is retained when the distal half of the rectum is preserved is illustrated by the following case.

A 64 year old man (Framingham Union Hospital No 77927) was found to have an annular grade 3 adenocarcinoma of the sigmoid 20 centimeters above the anus. There was in addition a malignant rectal polyp 5 centimeter in diameter located 10 centimeters above the

anus. At operation the tumor of the sigmoid was found to have invaded the serosa and 6 or 8 metastatic masses each about 2 centimeters in diameter were palpated in the liver. A palliative resection of the sigmoid and of the proximal half of the rectum was done. A rectosigmoidal anastomosis 7 centimeters above the anus was established by a modification of the "pull through" technique.

Since recovery from the operation the patient has noted absolutely no change in his ability to retain bowel contents by sphincteric contraction. Imminent defecation is associated with a normal perineal sensation which is in no way altered from the preoperative state. Bowel habits have not been changed and it has not been necessary to resort to cathartics enemas or change of dietary habits.

Preoperative and postoperative studies of the rectoanal reflexes are illustrated in Figure 5. Both studies were done with the double obturator. In graphs A obtained before operation the balloon was placed 10 centimeters above the anus and was filled and emptied by increments and decrements of 50 cubic centimeters each. Due to a considerable degree of overlapping of the internal sphincter by the external, the two graphs of sphincter activity show a superficial similarity. It is possible, however, to distinguish the sustained fall of internal sphincter tone resulting from filling of the balloon and the recovery of tone as the balloon is emptied. There is no sustained fall of the tone of the external sphincter and purposeful contractions of the external sphincter may be readily distinguished.

In graphs B obtained after operation it was necessary to use a smaller doughnut shaped balloon placed 5 centimeters above the anus. Because of the smaller area of rectum available for stimulation the balloon was filled and emptied by increments and decrements of 25 cubic centimeters each. Again the overlapping of one sphincter by the other makes the two graph lines superficially similar yet it is possible to distinguish the sustained fall of internal sphincter tone and the sharp momentary contractions of the external sphincter as the balloon is filled.

Both the clinical and experimental findings in this case indicate that sphincteric continence

is not compromised following rectosigmoidal resection when the distal 7 centimeters of rectum is retained.

E. Equivocal result following resection of the sigmoid and rectum with anastomosis 1 to 2 centimeters above the mucocutaneous line. A 60 year old man (Framingham Union Hospital No 78221) was found to have an early grade 2 adenocarcinoma of the rectum the lower border was 9 centimeters above the anus. The tumor was 3 centimeters in diameter, involved only about one third of the circumference of the rectum and was freely movable on the underlying tissues. At operation the distal half of the sigmoid and all of the rectum except the distal 1 to 2 centimeters were resected. Anastomosis of the proximal sigmoid and the retained rectum was established by a modification of the "pull through" technique. A transverse colostomy done at the time of the resection, was closed after the anastomosis had been properly dilated and was well healed. After healing was complete the line of anastomosis was found to be oblique, with 2 centimeters of rectum retained above the mucocutaneous line at the anterior commissure and only 1 centimeter above the mucocutaneous line at the posterior commissure.

For 30 years preceding operation, the patient required a cathartic two or three times a week, rarely having a bowel movement without such medication. Since recovery he has taken no cathartics and, two or three times weekly has had normal, soft, formed stools. The urge to defecate has been associated with an abdominal, cramp-like sensation which has given ample warning. Imminent defecation is now associated with a perineal sensation which is quantitatively less than the sensation he had before operation. There is also a qualitative difference in the sensation which he is unable to describe. The external sphincter can be voluntarily contracted with good force and the patient is not conscious of any loss of strength in this muscle. He believes himself to be continent although he makes no effort to control gas.

Preoperative studies of the rectoanal reflexes showed both the internal and external sphincters to respond normally when the rectum was stimulated with a balloon. Postop-

erative studies indicated that the voluntary sphincter contraction compared favorably in both strength and duration with those of many normal individuals. Numerous attempts to elicit the anal reflexes by stimulation of the remaining rectum the region of the anastomosis and the sigmoid immediately above the anastomosis were uniformly unsuccessful. These failures may be related to the mechanical difficulties of applying the stimulus to the small area of rectum that remains. The lumen of the sigmoid immediately above the anastomosis is relatively narrow as compared with that of the remaining rectum while the anastomosis itself contains scar tissue which is quite inelastic. When even the smallest doughnut shaped balloon is distended below the anastomosis it tends to push out through the anus and to interfere with the obturator. When a balloon is distended above the anastomosis it tends to migrate up the sigmoid unless forcibly held in place by traction on the attached catheter and even then appears to cause no stretching of the wall of the contiguous rectum because of the lack of resilience of the anastomosis. It is also possible that this failure to elicit the rectoanal reflexes is related to operative trauma to the afferent nerves arising in the remaining rectum. This seems unlikely because the perineal sensation that accompanies imminent defecation has not been abolished even though it is diminished in intensity and changed in quality. The diminished intensity of the sensation may be explained on the basis that almost complete resection of the rectum has eliminated most of the receptor units in which it arises. The change in quality of the sensation is more difficult to explain. It may be a faulty observation on the part of the patient.

In an effort to secure objective evidence of the persistence of sphincteric continence following operation a saline enema was given. During the injection small amounts leaked out through the anus on several occasions but was promptly controlled by sphincteric contraction. This observation suggested that the sphincter contracted only after fluid had entered the anal canal and thus too late to be controlled. After 500 cubic centimeters had been injected a strong urge to defecate was es-

tablished. When the patient was then allowed to get on his feet about 100 cubic centimeters leaked out through the anus coming in irregular spurts. The remaining fluid was retained for some time after which it was evacuated along with a large quantity of normal stool without difficulty.

At the present time 4 months after closure of the transverse colostomy the functional result in this patient remains equivocal. His ability to retain solid fecal material may well be the result of colonic continence which would have been retained even had the sphincters been sacrificed. Objective evidence of true sphincteric continence has not been obtained although the presence of a perineal sensation when defecation is imminent suggests that functioning afferent fibers are present in the small amount of rectum that remains. Theoretically these fibers should carry the impulses which give warning as to when sphincteric contraction is required. The observations made during and after the enema suggest that insufficient rectum and therefore insufficient afferent fibers have been retained adequately to initiate the rectoanal reflexes which appear to be essential to true sphincteric continence.

SUMMARY AND CONCLUSIONS

- 1 The essential difference between colonic continence and sphincteric continence is again stressed. The relative importance of each type of continence is discussed.
- 2 The results of physiological studies of the anal reflexes in 12 normal adults are presented.
 - A Stimulation of the sigmoid colon by means of an incrementally distended balloon caused no change in the tonus of either the internal or external anal sphincter.
 - B Stimulation of the upper rectum caused the characteristic reflex responses of both sphincters but the responses were feeble.
 - C The closer to the anus the stimulus was applied the more pronounced were the reflex changes of sphincter tone.
- 3 Clinical observations and physiological studies on 4 surgical patients with anastomoses at various levels of the rectum are presented.
 - A Resection of all of the rectum with anastomosis of sigmoid to anus at the level of the

mucocutaneous line resulted in loss of sphincteric continence and the rectoanal reflexes could not be elicited.

B Resection of the sigmoid colon with anastomosis performed at the level of the peritoneal reflection caused no change in rectoanal reflexes and there was no loss of sphincteric continence.

C Resection of the distal half of the sigmoid colon and the upper half of the rectum with anastomosis 7 centimeters above the mucocutaneous line caused no change in the rectoanal reflexes and no loss of sphincteric continence.

D Resection of the sigmoid colon and rectum with anastomosis 1 to 2 centimeters above the mucocutaneous line gave an equivocal result. The rectoanal reflexes were not elicited but this may be due to the mechanical difficulties associated with applying a stimulating balloon to the small amount of rectum that remains. It is probable however that sphinc-

teric continence is diminished to the point where it is of little practical value.

4. An intact reflex arc, with afferent fibers arising in the wall of the rectum and with efferent fibers terminating in the external anal sphincter is essential for the preservation of sphincteric continence. *The rectum is therefore an integral part of the sphincteric mechanism.*

5 The minimal amount of rectum that must be retained for the preservation of sphincteric continence has not been accurately determined. It would appear that at some point between 1 and 7 centimeters above the mucocutaneous line there is a level below which the rectum can not be resected without seriously interfering with the preservation of sphincteric continence.

RADICAL EXCISION OF THE INGUINAL AND ILIAC LYMPH GLANDS

A Study Based upon 450 Anatomical Dissections and upon Supportive Clinical Observations

EDWARD H DASELER, M.D., BARRY J ANSON Ph.D (Med.Sci.) and
ARTHUR F REIMANN M.D. Chicago, Illinois

THE location, grouping, size, and number of the inguinal and iliac groups of lymph glands are anatomical features of practical interest to all surgeons treating malignant lesions of the lower extremity, pelvis, and perineum, since metastatic involvement of these glands is a common occurrence. Relatively little has been written regarding variation in the location and extent of these glands and of structures associated with them. As a consequence, the surgical procedures which are advocated for their radical excision are likely to be generalized and inexact.

In an effort to establish a more dependable morphological basis for a procedure of choice, the authors studied the number, size, distribution, and fascial relations of the glands, and then sought to devise a technique which would be both surgically feasible and anatomically sound. It is their hope that the presentation of results will be of service in the treatment of malignancies affecting primarily the inguinal and the associated iliac glands.

MATERIAL AND METHODS

The anatomical observations were made on dissection of 450 anatomical specimens (American whites and negroes, preponderantly male). The records on the superficial inguinal lymph glands were taken concurrently with those on the saphenous venous tributaries which were reported in an earlier issue of this journal (Daseler, Anson, Reimann, and Beaton 1946).

Contribution No. 470 from the Anatomical Laboratory of Northwestern University Medical School.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-12, 1947.

A life-sized sketch of the subcutaneous veins of the inguofemoral region and the associated glands was prepared in each of the 450 thighs dissected. These have been employed to furnish data on distribution (Table I) and on size. Certain of the specimens representing typical arrangements, were selected for illustration (Figs. 1, 3, 4, and 5; specimens I to VII). The locations of the ten glands most commonly encountered were recorded diagrammatically (Fig. 2).

Having established patterns and relations by these means and following preliminary operating room observation, a technique for excision was further modified through the use of unfixed specimens.¹ Finally, the stages in the surgery were carried out on selected laboratory (embalmed) specimens, the steps being recorded by the artist (Figs. 6 to 8, specimen VIII). Subsequently, the method was employed by the senior author with satisfactory results. In the following account the authors will first present pertinent data on the glands, on related vessels, and on pelvofemoral layers, employing selected anatomic cases; then the technique of surgical extirpation and of repair will be discussed, as aided by the laboratory observations.

ANATOMICAL OBSERVATIONS AND DISCUSSION

I. GENERAL

The inguinal lymph nodes of superficial position are regularly described as being situated in the area bounded superiorly by the inguinal (Poupart's) ligament, inferiorly by a line cross-

¹The authors are indebted to Dr. Rolle MacCotter of the Department of Anatomy, University of Michigan, for the use of unfixed specimens in the perfection of the surgical techniques.

Average 8.5 lymph nodes per extremity

ing the point of intersection of the sartorius and adductor longus muscles laterally by a line dropped vertically from the anterior superior iliac spine and medially by a similar line commencing at the pubic tubercle.¹ However to be more exact in the 450 extremities examined during the course of the present study these glands were in all cases found within the confines of a quadrilateral area bounded as follows superiorly by a line 13 centimeters in

length parallel to and 1 centimeter above the inguinal ligament and beginning medially just above the pubic tubercle medially by a line 15 centimeters long dropped perpendicularly downward from the pubic tubercle laterally by a similar line 20 centimeters in length, dropped from the lateral limit of the superior boundary inferiorly by a transverse line 11 centimeters in length connecting the lower limits of the lateral and medial borders (see esp Fig 6)

The superficial inguinal glands, with the saphenous vein and its tributaries are situated within the deeper or typically membranous stratum of the superficial fascia of the thigh—the superficial fascia here being two-layered (Fig 1) just as it regularly is in the adjacent inguinal and perineal regions. The glands are covered by the superficial or fatty layer of the superficial fascia (Fig 3). In slightly obese specimens, when some fat occurs in the deeper or membranous layer the lymph nodes and the associated veins occupy the adipose lamella of the layer. But whether fibrous or partially fatty the stratum is easily separable from the subjacent fascia lata (Fig 1).

These superficial lymph glands send their efferent vessels into glands of deeper position, the latter situated along the femoral vessels within the fascial sleeve (fascia lata) of the thigh and into the iliac continuations of these vessels in the pelvis. These deep glands are lodged within the femoral sheath in tissue which passes without interruption into the retroperitoneal (subserous) tissue of the pelvic cavity (McVay and Anson, 1940). Within the pelvis this subserous tissue forms a stratum between the peritoneum and the parietal (obturator and iliac) fascia.

Of the two major sets the superficial offers the more difficult surgical problem, because of the relatively great expanse of their field the deep glands in being clustered about the iliac and femoral vessels, form simple elongate chains. The two sets will be considered separately.

2 SUPERFICIAL INGUINAL GLANDS

a. *Number size.* The superficial inguinal glands vary in number from 4 to 25 (Figs 5A to 5D). In the present series of 450 lower ex-

A comment on nomenclature is appropriate here. In standard descriptions all of the glands which occupy the proximal area of the thigh, over the femoral triangle, are termed *inguinal*. They are divided into two groups by a horizontal line which crosses the thigh at the point of termination of the great saphenous vein in the femoral; those lying above this line are termed the *superficial inguinal nodes*, and those below it the *subinguinal nodes*. The latter group is said to consist of superficial and deep sets.

The superficial inguinal nodes are immediately below the inguinal ligament; the superficial subinguinal glands are placed on either side of the upper part of the great saphenous vein. All of these glands are situated external to the fascia lata. The deep subinguinal nodes, unlike the glands constituting the preceding sets, are placed under the fascia lata, close to the femoral vein. They are described as if the maximal number were three (the lowest situated just below the junction of the great saphenous and femoral veins, the middle in the femoral canal, and the highest, termed the node of Cloquet or Rosenmüller in the femoral ring).

Actually, since but few nodes of the total series are in the inguinal region, rarely (as will be described) occurring along the base of the inguinal ligament or cranial thereto, the term *inguinal* is not suitable. And, although the name *subinguinal* would be serviceably descriptive, *femoral* would be wholly desirable. Moreover, the conventional division into *superficial* and *subinguinal* on the basis of relation to transverse line (at the saphenofemoral junction) is worse than arbitrary; it is entirely incorrect, since the area, between lower border of the external oblique aponeurosis and the femoral vein, is not inguinal.

As will become apparent through reading of the present authors' text, the usual scheme of Rosenber is anatomically sound. It will be followed in the current discussion. The term *superficial* will be retained, since it is, seemingly everywhere employed. The distinction between *superficial* and *deep* groups is, of course, fundamentally serviceable.

extremities 3 715 lymph nodes were encountered an average of 8 25 per extremity In size the individual lymph glands range between the surface area of 10 square centimeters and 0 6 square centimeter The size of the individual glands is usually inversely proportional to the total number of glands encountered in the individual thigh This statement would not, of course be applicable to cases in which the lymph glands were enlarged through malignant infiltration or suppurative involvement

b Zonal arrangement According to the system of Rouvière the superficial inguinal lymph glands are divisible into five groups in relation to areas bounded by horizontal and vertical lines for which the point of intersection is the saphenofemoral juncture The area is thus divided into four quadrants and a central, or fifth zone immediately overlying the saphenofemoral juncture (Fig 2) Von Bardeleben has stated that none of the five groups contains regularly more than 3 or 4 glands However as will be described later in the present series specimens were encountered in which as many as 9 lymph glands were present in a single zone (Figs 5a to 5d)

Zone 1 or the superolateral quadrant may contain no glands or as many as 8 lymph glands The individual nodes are usually elongate in an oblique line paralleling that of the inguinal ligament They are likely to be arranged in chain like formation situated slightly distal or inferolateral to the inguinal ligament and along the course of the superficial circumflex iliac vessels (Fig 5a) The lymph glands are more numerous here and more consistently present than in any of the other zones The members of this group of glands are described as receiving their afferent lymphatics from the skin of the upper gluteal region from that of the lateral and posterior abdomen below the level of the umbilicus and occasionally from the penile skin (or the homologous praeputium clitoridis of the female)

Zone 2 or the superomedial quadrant, may be free of glands or may contain them up to the number of 7 nodes They are usually circular in outline and clustered about the terminations of the superficial epigastric and superficial external pudendal veins (Figs 5a and 5b) The lymph glands of this group are said

to receive afferent cutaneous lymphatics from the following areas umbilical and infraumbilical portions of the abdomen, perineum and cutaneous anal area the scrotum the penile skin and praeputium clitoridis the vulva and portions of the external genitalia outside of the hymen and rarely from the glans penis and glans clitoridis (Rouvière) Cutaneous lymphatics from these regions though terminating in the superomedial group of glands have abundant anastomoses across the mid line they may therefore terminate in either the right or left side or in both Von Bardeleben has stated that none of the glands in either the superolateral or superomedial groups (zones 1 or 2) cross or lie cranial to the inguinal ligament The present authors, however have found several specimens in which a gland was situated above the level of the inguinal ligament, but never by a distance greater than 1 centimeter

Zone 3 or the inferomedial quadrant exhibits the same range in number of contained glands (none to 7) They are commonly elongate arranged with their long axes extending in a vertical direction It is in this quadrant that glands are most frequently absent (Figs 5c and 5d) in 173 of 450 extremities (38 per cent) lymph glands were wanting and in only 108 (24 per cent) was there more than one gland present The lymph glands of this group receive afferent lymphatics chiefly from the following source areas skin of the perineum, including the cutaneous anal area scrotum vulva the medial aspect of the thigh, leg and foot rarely from the glans penis glans clitoridis penile skin and praeputium clitoridis The lymphatics draining these regions likewise have abundant anastomoses across the mid line to the glands of the opposite side

Zone 4 the inferolateral quadrant, may contain no glands or as many as 9 These glands may be either rounded or oval in shape When of the latter form they are so placed as to have their long axes extending in a vertical direction They are grouped chiefly about the lateral accessory saphenous and the termination of the superficial circumflex iliac veins (Figs 5a and 5b) The glands in this zonal group receive their afferent channels chiefly from the skin of the anterior lateral, and posterior sur

lateral surface of the thigh, leg and foot from the skin of the caudal part of the gluteal region and occasionally from the skin of the perineum.

Zone 5, the central or presaphenous region immediately overlies the saphenofemoral junction (Figs. 5c and 5d). A single inconstant gland was found in this region in 68 of 450 extremities (15 per cent). This central or presaphenous gland may receive afferent lymphatics directly from the skin of the scrotum and penis (including the glans) in the male and the vulva (with the glans clitoridis) in the female. Additionally, it may receive wider perineal drainage as well as channels from any of the other zones.

As a group, the superficial inguinal lymph glands are drained by means of efferent lymphatics chiefly into the external iliac group of glands located along the course of the external iliac artery and vein. However, they may also empty into the deep inguinal glands which are situated beneath the fascia lata in the femoral triangle (see hereinafter).

Examination of statistical data growing out of tabular study of the records indicates that 10 lymph glands occur with great constancy (Fig. 2). The most constant individual gland encountered in the current series is one situated in the angle formed by the bifurcation of the lateral accessory saphenous from the great saphenous vein. This gland is absent in but 13.75 per cent of the cases. In the zone of this constant element, a single gland is present in 60.5 per cent of the cases studied; 2 glands in 22 per cent and 3 in 3.5 per cent. Another gland which occurs quite constantly in the authors' series (in 70 per cent of the cases) is one situated lateral to the lateral accessory saphenous vein and the gland mentioned above. A single gland but occasionally 2 or 3 glands (average 2) are frequently encountered (71 per cent of extremities) in an area from 2 to 3 centimeters lateral to and at the horizontal level of the saphenofemoral junction. A single gland or a chain of nodes numbering up to 9 (average 4) is most frequently encountered along the course of the superficial iliac circumflex vessels. Lymph glands are absent at the customary site of this chain in but 6 of the 450 extremities examined (1.33 per cent). A group consisting of from 1 to 7 glands (aver-

age 2) is almost constantly located medial and superior to the saphenofemoral juncture near the pubic tubercle. In this area glands are absent in but 9 per cent of the cases. In 183 cases (40 per cent) 1 gland is present; 2 are present in 144 cases (32 per cent); 3 in 58 (13 per cent); 4 in 15 (3.3 per cent); 5 in 4 specimens (1 per cent); 6 and 7 glands each in but a single case.

Before proceeding further with the discussion it might be well to recall that certain regions of the foot and leg, namely the lateral aspect of the foot, the heel and the posterior surface of the leg may drain directly into the popliteal glands. They are 2 to 4 in number and are located in the more distal portion of the popliteal space along the course of the posterior tibial and small saphenous vessels and near their junction with the popliteal vessels. When malignancies involve these areas, the popliteal as well as the inguinal glands should be excised.

c. Selected specimens. In order to establish the extent to which the inguinal glands vary in respect to number, relationship to superficial tributaries of the femoral vein and to group-distribution, seven specimens have been chosen for illustration (Figs. 1, 3, 4a to 4c, 5a to 5d). Each is a pictorial record of a dissection.

SPECIMEN 1 (Fig. 1)

Here as is invariably the case, the lymphatic glands are lodged in the deep membranous layer of the superficial fascia in the stratum with the saphenous vein and its tributaries. These structures become visible as soon as the superficial fat bearing layer of the superficial fascia has been reflected, however, for full exposure, enucleation from the tissue of the deep layer is required. That is to say they are imbedded in and do not merely rest upon the latter layer.

In this specimen the glands are large. Most of them are removed by greater than average distance from the saphenous vein and the fossa ovalis, none ascends to the level of the inguinal ligament. With the saphenous vein they outline a field of quadrilateral form.

The great saphenous vein enters the femoral vein at the distal end of the fossa ovalis as a

Fig 1. Anterior femoral region left thigh, specimen I. The superficial layer of the superficial fascia has been removed to reveal the deep layer with its contained inguinal lymph glands and the veins of the saphenous system to which the glands are intimately related. The deep layer has been incised and partially freed from the subjacent fascia lata.

short thick trunk which almost immediately receives large superficial epigastric and superficial circumflex iliac veins. The first of the two external pudendals enters just above the point of confluence of the great saphenous trunk and the lateral accessory saphenous vein the lower member of the pair terminates by entering on the medial aspect of the great saphenous vein distal to this confluence.

A large oval lymph gland is situated distal to the fossa ovalis lying lateral to and par-

tially covered by the lateral accessory saphenous vein (latter excised in Fig 1 to expose the gland). Two lymph glands one small and round the other of medium size and oval are situated 2 to 3 centimeters lateral to the saphenofemoral juncture. A single small oval gland is located distal to the superficial circumflex iliac vein while a large fused or S-shaped gland lies between this vein and the inguinal ligament. Two medium sized round lymph glands are located superior and medial to the

Fig. Saphenous vein and tributaries in relation to the ten inguinal glands of most frequent occurrence. The glands are separable into five groups: four of the groups are bounded by lines which meet at the saphenofemoral junction; the fifth group could be upon the vessels at the latter junction. 1, *vena circumflexa iliaca superficialis*; 2, *vena epigastrica superficialis*; 3, *vena pudenda externa*; 4, *vena saphena accessoria lat*; 5, *vena saphena magna*. Diagrammatic.

saphenofemoral junction in the angle formed by the superficial epigastric vein (excised in Fig. 1) and superficial circumflex iliac vein. A single large oval gland is situated just medial to the saphenofemoral junction, being crossed on its anterior surface by the first of the two external pudendal veins. A single small oval gland lies 3 centimeters medial to the great saphenous vein and 5 centimeters distal to the level of the saphenofemoral junction.

SPECIMEN II (Fig. 3)

On the right side three elongate glands situated in the angle formed by the saphenous vein and its lateral accessory. One large and two small lymph are situated along the course of and phalad to acial circumflex il. A large itly composed o fused no d immediately c saphenofe re h the external p dal emerge sa ovalis and

anterior to the great saphenous vein and its superficial epigastric tributary.

The great saphenous vein enters the femoral deep to the group of large fused lymph glands. On its medial aspect it receives a large superficial epigastric branch while on its lateral aspect it receives the fused common trunk formed by the lateral accessory saphenous and superficial circumflex iliac branches.

On the left side two lymph glands, one of them quite large are situated within the angle of the great and lateral accessory saphenous veins. Three elongate nodes are placed along the course of the superficial circumflex iliac vessels; they receive numerous small branches from them. Two small round glands are situated slightly superior and medial to the saphenofemoral junction. Finally a large slightly curved gland is located medial to the saphenofemoral junction in the angle formed by the great saphenous and superficial epigastric veins.

The external pudendal artery emerges from the fossa ovalis near its inferior margin and courses beneath the great saphenous vein to accompany the external pudendal vein. The superficial circumflex iliac artery escapes through a small foramen in the fascia lata just inferior to midportion of the inguinal ligament. Several small branches are given off to the adjacent glands as the artery accompanies its correspondent vein.

Near its junction with the femoral vein the great saphenous vein receives two large tributaries: one on each aspect, lateral and medial. Laterally the tributary vessel is the fused trunk of the lateral accessory saphenous and superficial circumflex iliac veins; the medial tributary is the superficial epigastric vein. The external pudendal vein reaches the femoral vein directly in the fossa ovalis from the medial side.

SPECIMEN

on the surface of the

Fig. 3. Anterior femoral and adjacent inguinal and pudendal regions, right and left sides, specimen II. The superficial fatty stratum is here left intact except where it contains lymphatic glands and blood vessels. The vessels have not been transected (as they were in Fig. 1) but exposed *in situ* by removing the immediately surrounding adipose tissue. In this way the extent of the lower abdominal, proximal femoral and pudendal areas of vascular and lymphatic drainage is depicted, and the fascial level of the glands and vessels recorded.

the other two regular branches (superficial iliac circumflex and superficial external pudendal) emerge through small foramina in the fascia lata each near the area of its ultimate supply.

The saphenous vein enters the femoral deep to the large superiorly placed lymph gland. On its lateral aspect the saphenous receives a large lateral accessory saphenous tributary and small veins from the superficial fascia and adjacent lymph glands. On the medial aspect the saphenous vein receives a superficial epigastric vein and two superficial external pudendal veins, the lower one of which enters by a common stem with a tributary draining the superficial tissue on the adductor side of the thigh.

On the left side at superficial level, are two unusually large glands which almost encircle the saphenous vein at its termination, five lesser glands, two of which extend superolaterally along the superficial iliac circumflex vein are also present (Fig. 4a). Efferent lymphatic vessels leave the upper member of the large pair of glands to gain the pelvis by passing through a small hiatus in the fascia lata situated just distal to the inguinal ligament. The margins of the fossa ovalis, the femoral artery and vein are completely obscured by the lymph glands and the saphenous vein (cf. Figs. 4b and 4c).

A single superficial epigastric and a superficial external pudendal artery arise from the femoral within the fossa ovalis, the superficial iliac circumflex emerges through a separate

Fig. 1. a. Anterior femoral and adjacent regions; specimen III. a. Right and left sides. The bifurcated superficial fascia has been removed to expose the inguinal lymph gland as they lie in relation to the blood vessels. b and c. Right and left sides, respectively, of the same specimen. The lymphatic glands have been removed in order to expose the femoral vessels in the fossa ovalis and the branches of the artery and the tributaries of the vein to which the glands were related.

iliac just inferior to the inguinal ligament and sends some of its twigs to the lymph glands.

The saphenous vein receives the three regular tributaries (epigastric iliac pudendal) in addition to several small branches from the superficial fascia and adjacent lymph glands.

On the right side at deeper level (with lymph gland removed) the fossa contained saphenous and femoral vein (Fig. 4b). The regular femoral artery and vein, the femoral artery being located next to femoral vein enters the femoral vein crotch between the femoral and superior aspects and

branch on the lateral and inferior sides. The superficial epigastric artery emerges from the fossa ovalis whereas the superficial circum-

flexa iliac artery emerges from the external pudendal artery nearby through the fossa ovalis. On the left side at comparable level the femoral artery contains the femoral vein on its inner aspect (Fig. 4c). The femoral artery arises from the aorta within the abdominal cavity and enters the femoral vein within the femoral sheath just inferior to the inguinal ligament point.

Fig 5 a to d. Anterior femoral region. Types of arrangement of the inguinal lymph glands: specimens IV to VII a, c, and d. Right groin: b, left groin: d.

beneath the saphenous vein to join the external pudendal vein.

SPECIMEN IV (Fig 5a)

A single large oval gland is situated within the angle formed by the great and lateral accessory saphenous veins. Another large oval gland is located on the outer aspect of the lateral accessory saphenous vein at the same level as the preceding. A group of six glands, two large and oval and four small and round, are placed 1 to 3 centimeters lateral to the saphenofemoral juncture. A group of three large glands, round and elongate, are located along the course of the superficial circumflex iliac vein. Three glands are situated superior and medial to the saphenofemoral juncture in the angle formed by the superficial epigastric, external pudendal, and great saphenous veins. Two glands are situated medial and inferior

to the saphenofemoral juncture. The first lies deep to the great saphenous vein at its juncture with the upper member of a pair of external pudendal tributaries; the second lies in the angle formed by the inferior member of the pair of veins and the great saphenous vein.

SPECIMEN V (Fig 5b)

As in the preceding specimen, a single large gland is located in the crotch bounded by the great and the lateral accessory saphenous veins. Lateral thereto is a gland of approximately the same size. Four smaller glands lie to the outer aspect of the saphenofemoral confluence. A single large gland is situated inferolateral to the superficial iliac circumflex vein, and five nodes lie in the triangular field between the latter vessel and the superficial epigastric vein. A single gland lies beneath the superficial external pudendal vein.

in surface area. In general, the lymph glands in zones 3 and 4 tend to be somewhat larger than those in zones 1, 2 and 5. These differences in size are, however, not constant and small glands are often found in zonal association and either kind may be found in any zone of an individual thigh. The average size of the outline of glands in the several zones is as follows: zone 1, 0.75 square centimeter; zone 2, 0.87 square centimeter; zone 3, 1.37 square centimeters; zone 4, 1.75 square centimeters; zone 5, 1 square centimeter in area. The lymph gland which is so regularly located in the angle formed by the great saphenous vein and its lateral accessory branch is consistently larger and more prominent than its mates.

3 DEEP INGUINAL GLANDS

a Number, size The deep glands are smaller as a lot, than the superficial. Their numbers vary, but usually they form an almost continuous chain separated only for reasons of topographical convenience from the iliac glands of the pelvis.

b Location and arrangement The glands follow the course of the femoral and deep femoral artery and vein. This means that they are subjacent to the fascia lata and chiefly in the femoral triangle. They may extend distally into the adductor canal, proximally the chain is prolonged beneath the inguinal ligament to merge with the members of the external iliac set.

The deep glands are lodged in the fatty tissue of femoral sheath. As already described and figured by McVay and Anson (1940), this adipose layer lies within the membranous tube which is regularly described as the femoral sheath. The membranous layer is a derivative of the abdominal and pelvic fascial layers—of the transversus and iliopsoas muscles respectively. It is carried downward into the thigh beneath the inguinal ligament, as the external iliac vessels become femoral (McVay and Anson Fig 5). Within this truly fascial sheath is situated the adipose layer; the latter is a derivative of the subserous (retroperitoneal) layer of the abdominopelvic cavity (McVay and Anson, Fig 7). Housed within this fat-filled stratum of connective tissue the

glands are simply clustered about the femoral vessels (Fig 7). The most constant and usually the largest member of this deep chain of nodes is the gland of Rosenmüller or Cloquet situated in the femoral canal beneath the inguinal ligament and medial to the vein. They are not separable into groups, since there exist neither femoral arterial rami nor corresponding venous tributaries which might serve as dependable boundaries for zones. Moreover, local concentrations of glands do not occur; the glands surround the femoral vessels in a scheme of rather even distribution. Consequently, a precise cataloguing of their relations is not possible.

Summarizing these observations, it may be said that the deep glands, in being clustered about the large vessels within the adipose stratum of the femoral sheath are arranged in the form of a chain from one specimen to another; they exhibit no marked variation in grouping or important difference in number. Usually they are of small or of medium size.

4 ILIAC (PELVIC) GLANDS

The iliac glands are associated with the external iliac, hypogastric (internal iliac) and common iliac blood vessels, and are correspondingly named. Those distally placed are continuous with the nodes of the inguinal set while the glands situated proximally are continuous with the aortic (lumbar) nodes—the three sets being separable only upon topographical basis. In regard to number and position they conform to the standard descriptions.

The external iliac nodes are 8 to 10 in number; the hypogastric usually 8; the common iliac glands 4 to 6. The glands of the three sets are found chiefly along the sides of the vessels. Of the external iliac group a single gland may rest upon the medial aspect of either artery or vein or in the sulcus between the vessels; the hypogastric glands are similarly related to the hypogastric vessels and their larger arterial branches and venous tributaries of the common iliac set; 1 or more may be partially concealed by the vessels (i.e., lie dorsal to them) and an equal number appear below the bifurcation of the aorta, upon the fifth lumbar vertebra. All of the iliac and

Fig. 6, a and b. Technique of surgical exposure of the inguinal lymph glands, carried out on an anatomical basis, specimen VIII. a, Direction and extent of surgical incision. Shaded regions indicate the extent to which skin flaps should be undermined. b, Surgical procedure, continued. Showing the structures contained in the quadrilateral block of tissue excised in the radical extirpation of the glands, and the associated veins and the fascia in which the superficial glands and vessels are imbedded. The quadrilateral area is outlined, its superior limit marked by an arrow. Proximally, in the area of the fons ovalis (saphenous opening), the bilaminar superficial fascia has been removed, exposing the deep fascia (fascia lata) distally just beyond the apex of the femoral triangle, both superficial and deep layers have been incised and turned upward together exposing the subjacent musculature.

Continuing in the procedure here illustrated by dissections of selected specimens the skin over the anterior surface of the upper

thigh and lower abdomen is to be excised. Similarly the superficial fascia and the fascia lata are to be removed (Fig 6b block of tis-

Fig. 7 Procedure, continued, same specimen (VIII). Illustrating the method of removing the deep inguinal glands, by opening the fibrous layer of the femoral sheath and excising the gland-bearing fatty layer (retracted in several portions) which surrounds the femoral vessels.

sus outlined by dotted lines) The quadrangular block is 5 inches wide and 8 inches long. In the region of the fossa ovalis the superficial fatty tissue overlying the great saphenous vein and its tributaries and the superficial inguinal lymph glands, is removed. The dissection is begun at the lower end of the quadrilateral block the great saphenous vein being doubly ligated and severed. Then the incision is carried deeply to the level of the underlying musculature of the thigh. The block removal of these tissues continues in a cephalad direction.

In the next step of the procedure the quadrilateral block of tissue consisting of the su-

perficial and fascial layers with contained saphenous vessels and all superficial inguinal lymph nodes is excised, exposing the underlying musculature of the thigh in the femoral triangle (Fig. 7). Beginning at the apex of the femoral triangle, the femoral sheath, with the contained gland-bearing adipose tissue, is progressively removed in this way the femoral vessels their circumflex and deep branches and the femoral nerve are entirely freed of their surrounding fibroadipose tissues. The several muscular rami (to the pectineus, iliopectineal quadratus femoris, and adductor muscles) should be ligated and severed in order to facilitate this phase of the surgical dissection.

and sever the inferior epigastric and deep circumflex iliac branches of the external iliac artery and the corresponding veins. The spermatic cord with the contained spermatic artery, pampiniform plexus and ductus deferens is to be retracted medially by means of a Penrose drain. Starting superiorly near the bifurcation of the abdominal aorta, the investing sheaths of the common and external iliac and hypogastric vessels, together with the surrounding gland-bearing fibroadipose tissues should be stripped away down to the level of the inguinal ligament. The obturator nerve and vessels also made visible, are to be freed of all the fibrous tissue in which they are imbedded. Here care should be taken to avoid injury to anomalous obturator vessels arising from the external iliac artery and vein (see Ashley and Anson 1941).

In closing the inguinal portion of the surgery the hernial technique devised by McVay and Anson (1942) has been successfully employed in the senior author's cases. The fused aponeurotic portions of the internal oblique and transversus abdominis muscles and the underlying transversalis fascia are approximated to the superior pubic (Cooper's) ligament by means of six steel wire sutures (Fig. 8b). This approximation is carried lateralward from the pubic tubercle to the medial edge of the external iliac vein. The external oblique aponeurosis, which was previously split in the direction of its fibers, is next reconstructed in its lateral portion by means of interrupted steel wire sutures. At this stage the deeply situated external iliac artery and vein are clearly visible and the spermatic cord lies free on the anterior surface of the proximal thigh. In completing this repair the spermatic cord should be placed in the trough-like furrow created by approximation of the so called conjoint tendon and superior pubic ligament. The external oblique aponeurosis is then restored above the cord in order to reconstruct the subcutaneous inguinal ring at a point just medial to the pubic tubercle. If the vascular supply to the widely undermined skin flaps appears adequate, these flaps may be ap-

proximated. Penrose drains are placed (to promote drainage) at either end of the incision. If however viability of the flaps appears doubtful then wide excision of the skin flaps is carried out and closure effected through the use of a broad based pedicle flap and a split thickness graft. Postoperative refrigeration has also proved of value in preserving the viability of the cutaneous flaps.

SUMMARY

On the basis of an anatomical study of 450 dissection room specimens, data on the size, arrangement and number of the inguinal and associated pelvic glands have been presented, with the object of placing these morphological facts upon schematic and statistical bases. Certain types were found to predominate in relation to regular tributaries of the saphenous vein and to the femoral and external iliac vessels. Additionally several representative specimens have been illustrated and described in detail in order to account more satisfactorily for the anatomical conditions encountered in individual bodies.

A surgical technique has been described together with drawings of the steps involved. This procedure is the outcome not only of the antecedent observations on anatomic arrangement of the glands and associated structures, but also of the actual surgical employment of the selected method.

INTRA-ARTERIAL TRANSFUSION

Experimental and Clinical Considerations

ROY L. ROBERTSON M.D. IRVIN H. TRINCHER, M.D. and
EDWARD W. DENNIS B.S. Atlanta, Georgia

THE restoration of blood volume and pressure in the treatment of acute hemorrhage and traumatic shock is a fundamental surgical procedure will determine in large part the immediate course and prognosis particularly with regard to cerebral function and the prevention of anuria and myocardial anoxia. The procedures currently in use are concerned primarily with replacement of blood volume rather than restoration of pressure which occurs secondarily. The purpose of this paper is to present experimental and clinical data concerning a method for the simultaneous rapid restoration of blood volume and pressure utilizing the intra arterial route of administration.

The administration of fluids intra arterially was reported as early as 1937. Hypertonic solutions of sodium chloride were used in the treatment of shock by Davis and associates. Kendrick and Wakim in their work on dogs found this solution to be deleterious in that the rise of blood pressure was transitory and the animals would not respond to subsequent injections. The intra arterial method for administration of blood was employed with success by I. A. Birillo in his report appearing in a Russian journal in 1939. In this country the intra arterial route for the infusion of plasma and blood was first used by Kohlstaedt and Page upon the suggestion of Colonel Sam F. Seeley, Medical Corps U. S. Army. Their clinical procedure was based upon animal experiments in which they compared the efficacy of intra arterial and intravenous infusion of blood in experimental shock. Standardized hemorrhagic shock was produced in dogs by

arterial bleeding until a mean arterial pressure of 50 millimeters of mercury was reached. This pressure was maintained for a period of 90 minutes and then cautiously reduced to 30 millimeters of mercury and kept at that level for 45 minutes. In one group the total volume of blood removed was returned intra arterially and intravenously. The results showed a survival rate of 100 per cent for the intra arterial group as compared with 75 per cent for the intravenous group. In a second group in which only half the blood removed was reinfused 75 per cent of the intra arterial group survived whereas only 30 per cent of the intravenous group recovered. Clinically infusion of solutions other than whole blood caused sloughing of skin in the area supplied by the artery presumably due to prolonged ischemia.

Later work by Glasser and Page evaluating prognostic signs in hemorrhagic shock, further demonstrated the efficiency of intra arterial infusion. Moreover they found that when large infusions of blood are required to restore pressure and volume, the prognosis is poor the same is true for a falling pressure upon termination of the infusion. These authors observed the effect of ouabain upon the survival rate of animals in shock receiving intra arterial transfusion. The increased survival rates with the use of this rapidly digitalizing drug suggests that the drugs of this group might have a beneficial effect upon the myocardial depression seen in prolonged shock (10).

Shaffer has recently reported that in attempting the administration of transfusions occasionally placed within the femoral artery and the infusion completed with no untoward results. Kay and Hacker described the successful use of intra aortic transfusion by direct puncture during the course of an exploratory thoracotomy for control of hemorrhage from a lacerated internal mammary artery.

This project received financial support from the Medical Department, United States Army.

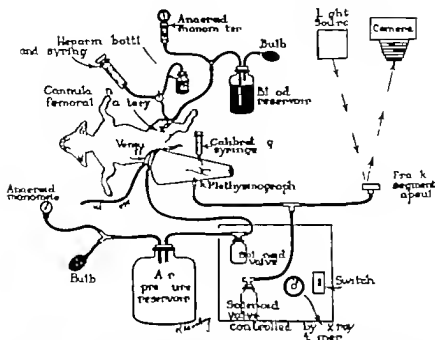

Fig. Diagrammatic sketch of equipment used to measure blood pressure and flow in dogs while state of hypotension is produced. Plethysmograph, solenoid valves for control of cuff inflation and elimination of cuff artifact, and system of optical recording are shown. One limb of the dog is shown with femoral artery cannulated for hemorrhage and reinfusion.

Controlled hypotension by arterial bleeding has been used by Gardner to attain a relatively bloodless field in certain neurosurgical procedures. Blood is removed by cannulation of a peripheral artery and replaced intra arterially at will during or upon completion of the procedure.

In the light of this previous work intra arterial transfusion appeared to have a place in the treatment of shock. Accordingly the demonstration of the effectiveness of the intra arterial transfusion experimentally has led to its clinical application.

The transfusion of blood intra arterially is based upon the hydraulic principles of Archimedes. Under a pressure greater than that of the mean arterial blood pressure an infusion will enter the arterial system. The increased pressure and flow will be conducted throughout the entire system as far proximally as the aortic valves. There will be an immediate increase in arterial pressure and blood volume. Under the conditions of shock, in which there is a lowered blood pressure decreased blood

volume and reduced tissue perfusion an intra arterial infusion will act to restore to normal levels all three deficiencies.

EXPERIMENTAL PROCEDURE

In the experimental work with intra arterial and intravenous transfusions, an attempt was made to correlate not only blood pressure changes and visible response with the route of administration but to secure some quantitative measurement of tissue perfusion. Blood flow to an extremity was selected as a criterion for determining changes in the peripheral blood flow on the premise that since this flow is restored late in the correction of hemorrhagic shock, flow to vital centers probably has already been restored.

In the dog blood flow to a hind limb was measured after the method of Eckstein and associates a small air plethysmograph being used the measurements were recorded optically with a large segment capsule (Fig. 1). Arterial blood pressures were recorded optically by means of Hamilton manometers. The

Fig. 2. Blood pressure and blood flow tracings demonstrating progressive vasoconstriction in hemorrhagic hypotension and shock in dogs. Blood pressure is recorded optically using Hamilton manometers; the readings are in millimeters of mercury. Blood flow curves are superimposed on the arterial tracings. The values indicate cubic centimeters of blood per 100 cubic centimeters limb per minute. Time: 0.2 second. a, Normal; b, hemorrhage begun; c, shock—10 minutes; d, shock—45 minutes.

following procedure was used: adult dogs weighing 10 to 20 kilograms were anesthetized with intravenous sodium pentobarbital (30 milligrams per kilogram of weight). One hind limb was sealed in the plethysmograph with melted printer's mica compound. The opposite femoral artery was cannulated for controlled hemorrhage, pressure readings, and the reinfusion of blood. In some experiments, other arteries such as the carotid or radial were cannulated for pressure determination. After a basal period of 30 to 35 minutes normal blood pressures and flows were recorded. The animals were then bled rapidly into a bottle containing 2.5 per cent citrate solution until the mean arterial pressure reached 50 millimeters of mercury. The blood pressure was kept at this level by repeated small hemorrhages. During the period of hemorrhage and the ensuing period of hypotension, serial blood pressure and flow measurements were made (Fig. 2).

Hemorrhagic hypotension was maintained for intervals varying from 30 to 75 minutes. At the end of this interval, all the blood removed was reinfused: one group of animals received the infusion by the intra arterial route, another intravenously. In the intra arterial group the blood was reinfused at a pressure approximately 50 millimeters of mercury greater than the mean blood pressure; air pressure

above the blood in the infusion reservoir was used. Infusion rates by this route averaged about 100 cubic centimeters per minute.

The intravenous infusions were allowed to flow by gravity at a rate which was substantially greater than that used in the routine clinical administration of blood, and which was considered to approach the maximum pressure

TABLE I—RESULTS OF REINFUSION OF BLOOD IN DOGS BY INTRA ARTERIAL AND INTRA VENOUS ROUTES

Animal N	Normal values	Time in shock, min.	Shock values	Time for recovery, min.	Recovery values	Result
Intra-arterial transfusion						
1	6.6 120/105	45	0.8 60/40	10	6.3 125/90	Survived
2	4.4 100/30	25	0.3 55/35	8	5.5 105/95	Died—Dx.
33	5.1 150/30	60	0.5 75/55	7	0 120/100	Survived
53	0.6 100/140	45	0.6 70/30	4	0.3 100/110	Survived
7	12.0 150/0	20	0.3 55/40	7	4.2 0/85	Survived
Intravenous transfusion						
1	6.1 120/100	30	0.6 65/45	18	5.9 1 5/85	Survived
2	3.4 120/92	60	0.6 55/44	18	6.5 1 5/90	Survived
6	6.5 115/96	45	4 60/50	20	5.8 0.5/74	Survived

*Rapid intravenous infusion, 100 c.c. returned in 6 minutes.

Fig 4 Restoration of pressure and flow with intra-arterial transfusion in dog—500 cubic centimeters of blood given in 6 minutes. The time required to restore the pressure and flow is 4 to 5 times less than that required by the administration of blood intravenously. a, Intra-arterial transfusion, 1 minute 325 cubic centimeters, b, 3 minutes 300 cubic centimeters. c, transfusion completed, 6 minutes, 500 cubic centimeters. d 45 minutes after transfusion begun

Following intravenous transfusions, recovery was considerably slower, requiring a period approximately four times longer than that required after intra arterial transfusion. There was also a tendency for blood pressure and flow to be maintained at a lower level than normal after the transfusion was completed.

In general these results were in agreement with the more extensive work of Kohlstaedt and Page, but differed in that the period of hypotension in these experiments was shorter and in each instance all the blood removed was re-infused.

All of the animals survived indefinitely except for one which died of distemper 2 days after an intra arterial experiment. No ill effects were observed following either procedure. In one instance (dog 7 Table I) a comparison of the two methods of transfusion carried out several weeks apart on the same animal is afforded.

CLINICAL APPLICATION

The clinical application of the intra arterial transfusion at Emory University Hospital and Grady Memorial Hospital has followed the technique developed experimentally by Kohlstaedt and Page. The dramatic results demonstrated in the laboratories on animals in experimental shock led to its introduction clinically.

The apparatus is simple and easily assembled from materials found in any hospital blood bank (Fig 5). The blood is contained in a 1000 cubic centimeter Kelly bottle from which it flows through a glass Y to the cannulated artery and an aneroid manometer unit. Controlled air pressure from a sphygmomanometer bulb applied above the blood in the reservoir permits the pressure within the entire system to be maintained at any desired level.

The aneroid manometer unit provides an interface between the sterile and unsterile parts of the apparatus, as shown in Figure 5. The sterile rubber stopper with attached finger from a surgeon's glove is placed loosely in the glass tube. A 2.5 per cent sodium citrate solution is poured into the reservoir and allowed to fill the tubing. When the level of the solution has risen to 2 centimeters in the manometer tube the rubber stopper is pressed in firmly. An increase in hydraulic pressure within the system will be transmitted to the air above the solution and be recorded by the aneroid gauge.

The apparatus except the rubber bulb and aneroid gauge, is wrapped as a unit on a tray and autoclaved. Prior to use the entire system is assembled clamped in place with double-ended clamps, and filled with citrate solution. Blood is transferred from the collecting bottles by filtering through layers of sterile gauze.

TABLE II.—RESULTS OF INTRA-ARTERIAL TRANSFUSION IN CLINICAL CASES

Case Sex Age	Condition predisposing to shock	Blood pressure at beginning of transfusion	Blood pressure at completion of transfusion	Volume of whole blood transfused— c.c.	Time re- quired for administration— min.	Artery used	Result
F 30	Septicemia with peripheral circulatory collapse			20 phases	20	Radial	Died
F 40	Uterine hemorrhage		90/60	250	5	Radial	Survived
F 30	Cesareanotomy with operative hemorrhage		100/70	1000	40	Post tibial	Survived
F 30	Rupture of aortic aneurysm		100/65	500	20	Radial	Survived*
M 35	Intestinal obstruction, neglected pulmo- nary tuberculosis	40/0	35/50	500	45	Radial	Died
F 40	Placenta previa with hemorrhage		100/75	1000	30	Radial	Survived
M 40	Rupture of aneurysm		130/60	1000	40	Radial	Survived
F 35	Gonorrheal wound of the abdomen	60/30	130/70	500	40	Radial	Survived
M 40	Secondary hemorrhage in pericardial abscess		60/40	750	30	Radial	Survived
M 35	Hemorrhage from gastrojejunal anastomosis	45/30	100/60	500	30	Radial	Survived†
F 30	Nephrectomy for hypernephroma with operative hemorrhage		100/60 100/75	1000 500	40 60	Radial Post tibial	Shut in hour Survived‡
M 60	Transurethral prostatictomy with post- operative hemorrhage		10/50	500	15	Radial	Survived‡

* Patient died 3 days later from secondary rupture of the aneurysm.

† Transfusion was given to stabilize blood pressure during an operative procedure in a patient with incipient shock and decreased blood volume.

‡ Patient showed signs of shock 1 hour after termination of the first intra-arterial transfusion.

§ Patient died 5 hours later from secondary hemorrhage.

The radial, dorsalis pedis, and posterior tibial arteries are used most frequently for intra-arterial transfusion. The vessel is exposed and a small longitudinal incision is made in its wall through which the cannula is introduced and directed proximally. A distal ligature is tied to prevent back bleeding. Any type metal or glass cannula of 14 or 15 gauge may be used. Upon release of the clamp behind the cannula the pressure within the patient's arterial system may be read immediately on the aneroid gauge.

Depending upon the pressure noted in the cannulated artery the condition of the patient and the former blood pressure if known the pressure necessary for transfusion can be estimated. In patients with no perceptible blood

pressure the transfusion should be initiated at a pressure of 50 millimeters of mercury. The previously estimated optimum pressure may be reached rapidly in successive increments of pressure.

The rapidity with which the transfusion will flow is dependent upon the differential in pressure between that in the reservoir and the patient's arterial system. As the patient's arterial pressure rises there is a diminution in both velocity and volume of flow through the cannula approaching zero as the pressures equalize. By maintaining a constant head of pressure in the transfusion reservoir the arterial pressure can be controlled within narrow limits.

To date 13 intra-arterial transfusions have been given (Table II). The case reports are

ROBERTSON ET AL. INTRA ARTERIAL TRANSFUSION

Fig. 5. Diagrammatic sketch showing essential parts of apparatus used clinically for intra-arterial transfusion. Inset shows detail of sterile interface in the manometer unit for continuous recording of pressure within apparatus and cannulated artery.

presented to illustrate the effects of the transfusions under different conditions.

CASE 1. A 50 year old woman with an overwhelming septicemia developed peripheral circulatory collapse and had no perceptible blood pressure. Although she was not considered a proper candidate for an intra-arterial transfusion an attempt was made to restore her blood pressure by an infusion of 350 cubic centimeters of plasma in the right radial artery in 10 minutes. The patient showed no improvement and died despite all restorative measures attempted.

CASE 2. A 40 year old woman with a submucous leiomyoma of the uterus had lost a large amount of blood prior to admission to the hospital. During her stay in the hospital in preparation for operation she developed profound shock from the uterine cavity and had a brisk hemorrhage from the uterine cavity and consciousness and no perceptible blood pressure. She received 250 cubic centimeters of blood in the left radial artery in 15 minutes with a dramatic rise in blood pressure to 95/60 and subsequent recovery from shock. A hysterectomy was later performed with no complications.

CASE 3. During a craniotomy performed on a 30 year old woman the patient's blood pressure and pulse became imperceptible. With every known measure taken to restore her blood pressure she still

did not respond. An intra-arterial transfusion of 1000 cubic centimeters of blood was given via the right posterior tibial artery. Although the transfusion was administered over a period of 40 minutes there was immediate response. The patient's blood pressure rose to 100/70 and her pulse slowed to 130. The operation was successfully completed.

CASE 4. Following operation for a patent ductus arteriosus this 12 year old female child developed a mycotic aneurysm. During operation for correction of the defect the aneurysm ruptured. The patient rapidly lost a large amount of blood leading to profound shock. She received 500 cubic centimeters of blood in the right radial artery in 20 minutes with a rapid return of perceptible pulse and blood pressure which became stabilized at 100/65. She survived the operative procedure, but died 3 days later of a secondary rupture of the aneurysm.

CASE 5. A 55 year old male known to have active pulmonary tuberculosis was admitted to the hospital with intestinal obstruction of several days duration. He developed increasingly profound shock with a blood pressure of 40/0. During the administration of 1500 cubic centimeters of whole blood via the radial artery he showed all of the clinical responses to an intra-arterial transfusion in that his blood pressure became perceptible and his pulse and respiratory rate decreased. Skin temperature readings taken on the toes showed a rise of 5 to 10 degrees F.

Fig. 6 Case 6. Graph showing relation of quantity of blood transfused to rise in blood pressure and fall in pulse rate plotted on a time scale. Intra-arterial transfusion in placenta previa hemorrhage.

However this patient had irreversible changes due not only to prolonged shock but also to pulmonary disease and long-standing intestinal obstruction. After completion of the transfusion in 45 minutes, blood pressure and cardiac output were not maintained and he died approximately half an hour after termination of the transfusion. Necropsy showed pneumonia and gangrenous bowel.

CASE 6. This 33 year old primipara with placenta previa developed uncontrollable bleeding. An emergency cesarean section was performed to terminate the pregnancy and control hemorrhage. Two 500 cubic centimeter intravenous transfusions were begun but the patient showed no response. She had lost about 3000 cubic centimeters of blood and was in profound shock. An intra-arterial transfusion was begun while the intravenous transfusions were still being given. The patient had responded well by the time 300 cubic centimeters of whole blood had been forced into the left radial artery. She received a total of 1000 cubic centimeters of blood intra-arterially in 50 minutes and survived. Figure 6 gives a graphic representation of the response to the intra-arterial transfusion as plotted on a time scale, showing the pulse rate, diastolic and systolic pressures and the volume of blood infused.

CASE 7. A 40 year old negro male underwent surgery for ligation of an aneurysm of the left subclavian artery. During the operative procedure the

aneurysm ruptured with severe hemorrhage and an estimated loss of 3500 cubic centimeters of blood. Administration of two 500 cubic centimeter blood transfusions was begun intravenously. Within 10 minutes this patient did not have a perceptible pulse or blood pressure and developed gasping respirations. At this point 5000 cubic centimeters of whole blood were transfused into the right radial artery over a period of 40 minutes. There was a rapid rise in blood pressure which was maintained at 130/60 during the operation and after the procedure was completed.

CASE 8. A 36 year old negro female was admitted with a single gunshot wound of the abdomen. She was in shock upon admission, but responded well to intravenous saline and glucose and 1000 cubic centimeters of whole blood intravenously. In the operating room, when anesthesia was induced, the patient's blood pressure dropped suddenly to 70/40. Two intravenous transfusions were started, and after 25 minutes 600 cubic centimeters of blood had been administered. The blood pressure remained at 60/30 with rapid pulse and shallow respirations. An intra-arterial transfusion was begun in the right radial artery and within 15 minutes 500 cubic centimeters of blood had been given, with a rise in pressure to 90/60. In the next 15 minutes the patient received an additional 1000 cubic centimeters of blood and her blood pressure rose to 130/70. The patient sur

vived the closure of two perforations of the small intestine, and maintained a blood pressure of 130/85 throughout the procedure.

CASE 9. A 46 year old male diabetic, isopropyl alcohol addict was admitted for drainage of the small perinephritic abscess. In the course of 23 hospital days 3 operations were performed under general anesthesia for incision and drainage because of persistent localization. Five days after the third drainage the patient suddenly began to bleed from the operative wound. There was an estimated loss of 2500 cubic centimeters resulting in profound shock. Despite two 500 cubic centimeter intravenous transfusions given as rapidly as possible the patient became moribund with gasping respirations and marked cyanosis. An intra arterial transfusion was begun in the left radial artery while the patient was prepared for a fourth exploration under light cyclopropane anesthesia. A total of 1750 cubic centimeters of blood was given over a period of 30 minutes. The patient rapidly improved blood pressure stabilized at 100/60 the color became good and respirations were deep. A nephrectomy was performed and recovery was uneventful.

CASE 10. A 53 year old negro male was admitted for esophagotomy because of suspected esophageal stricture. Six years previously he had undergone subtotal gastrectomy for benign peptic ulcer with obstruction. While in the hospital he developed melena which persisted for a month with frequent blood losses of 500 to 750 cubic centimeters and a distal obstruction of the stomach with spasm. Forty Roentgenograms demonstrated a partial obstruction of the bleeding point was considered imperative. An exploratory laparotomy was performed under continuous spinal anesthesia. The left radial artery was cannulated and intermittent intra arterial transfusions were given throughout the operative period. A total of 1500 cubic centimeters of blood was infused over the two hour period and the blood pressure was stabilized at 100/60. Each time a trend toward a fall in pressure was noted the rate of blood flow into the artery was increased. The patient with critical condition. Surgery consisted of gastrotomy, second anterior gastroenterostomy and establishment of a unieutal except for postoperative intestinal obstruction 7 days later.

CASE 11. A nephrectomy was performed on a 50 year old woman for a large hypernephroma of the right kidney. The kidney and tumor together approximated the size of the patient's liver. Due to the technical difficulties involved in the removal of the mass the patient was under anesthesia for 4 hours. Throughout the operation the patient had frequent extra systoles and manifested shock when ever the peritoneal contents were handled. In the course of the 4 hours the patient had received 1000 cubic centimeters of whole blood intravenously as

well as 1000 cubic centimeters of normal saline. Toward the end of the fourth hour the patient's blood pressure became imperceptible, the pulse rapid and irregular. An intra arterial transfusion was started in the right radial artery and 1000 cubic centimeters of blood administered within 40 minutes. The patient's blood pressure rose to 110/90 and her condition improved to the point where she was considered to be out of danger. The needle was removed from the radial artery, the artery was ligated and the wound closed. The patient did well for almost an hour but at the end of this period showed progressive signs of impending shock. She was given 10 cubic centimeters of adrenal cortical extract (25 rat units) intravenously and cardiac stimulants without effect. During this interval, a 500 cubic centimeter intravenous transfusion was given. At the end of the hour the patient's blood pressure was again imperceptible and the pulse thready. A second intra arterial transfusion was begun in the left posterior tibial artery. In the next hour the patient received 1500 cubic centimeters of blood intra arterially at a mean pressure of 150 millimeters of mercury. An additional 10 cubic centimeters of adrenal cortical extract and 0.25 milligram of ouabain were injected intra arterially during the course of transfusion. When the transfusion was completed the patient's blood pressure was 100/75 pulse strong but irregular respirations 20 per minute color good and extremities warm. The patient survived and excreted 800 cubic centimeters of concentrated urine from her remaining kidney during the first 24 hours.

CASE 12. Transurethral prostatectomy for vesical neck obstruction was performed on a 60 year old male. During the course of the procedure arterial bleeding was troublesome and required frequent and extensive coagulation. Within the first 24 hours there was only minimal bleeding. However on the second postoperative day the patient began to pass large amounts of blood through the indwelling catheter with a resulting fall in blood pressure from 140/90 to 60/30, in spite of almost continuous intravenous transfusion. Approximately 60 hours after operation he underwent suprapubic cystostomy for control of the hemorrhage. Blood loss prior to cystostomy was estimated to be 3000 cubic centimeters with an additional loss of 4000 cubic centimeters during the procedure. He had received 6500 cubic centimeters of blood intravenously, a portion of this rapidly using pressure technique. One hour and twenty minutes after cystostomy was begun his blood pressure became imperceptible and his pulse rate 90 but thready. An intra arterial transfusion was started in the right radial artery and 400 cubic centimeters of blood administered at 120 millimeters of mercury in 12 minutes. The blood pressure in the opposite arm was recorded as 90/60. In the course of the next 40 minutes an additional transfusion of 1000 cubic centimeters of blood was given intra arterially resulting in a stabilized pressure of 110/60. The hemorrhage was partially controlled and operation completed. Postoperatively the patient's blood

pressure remained around 110/60 for 5 hours, during which time no further transfusions were given. At this point a profuse hemorrhage occurred in the operative wound, and the patient expired before additional blood could be given.

DISCUSSION

The clinical results of intra arterial transfusion have closely paralleled the observations made upon laboratory animals. The pressure responses, the volume of blood needed for response, and the survival criteria are identical as shown in the case histories and in Table II.

The results of our experimental and clinical use of blood transfusion by the intra arterial route have substantiated the premise upon which the earlier investigators worked that is an immediate and sustained response is effected, with rapid rise in blood pressure and restoration of blood volume. A similar result may be secured experimentally with administration of blood intravenously under pressure however the time required for administration and response is considerably longer and the danger of cardiac embarrassment ever present.

With the clinical experience to date, intra arterial transfusion should find a definite place in the treatment of shock. There are however well-defined limitations for its use.

Indications Administration of blood by this method is indicated primarily in the treatment of shock resulting from a rapid decrease in blood volume severe traumatic shock which fails to respond adequately to conventional therapy exsanguination in obstetric emergencies, intra abdominal and intra thoracic hemorrhage. Anesthetic emergencies and asphyxia may also respond to intra-arterial transfusion. It is recommended that other measures to combat shock or hemorrhage such as the administration of stimulants, oxygen intravenous infusion and transfusion be used simultaneously.

Contraindications Intra arterial transfusion involves the sacrifice of an artery and is a

procedure which should be reserved for extreme emergencies after conventional methods of therapy have failed to effect a satisfactory response.

This procedure does not lend itself to the treatment of the terminal stages of acute or chronic disease in which a response might be only transitory as demonstrated in Cases 1 and 5 (Table II) in which the patients died after an initial response to the transfusion. The wisdom of an intra arterial transfusion in the presence of heart disease or heart failure is debatable.

Active bleeding from a wound, peptic ulcer or traumatized organ is not in itself a contraindication for intra arterial transfusion, provided there is a possibility of control of the hemorrhage. It is obvious, however that with this, as with any other procedure for replacement of blood continued or recurrent hemorrhage will vitiate whatever improvement has occurred, as seen in Case 12.

SUMMARY

A method for the rapid administration of blood intra-arterially is presented with experimental observations and report of its clinical application in 12 patients. This procedure can be lifesaving in cases of extreme emergency where the outcome may otherwise be fatal because of hemorrhage and shock.

URINARY TRACT CHANGES IN CERVICAL CARCINOMA

WILLIAM K. DIEHL, M.D., F.A.C.S. and J. MASON HUNDLEY, Jr. M.D., F.A.C.S.
Baltimore, Maryland

IN 1858 Wagner reported the presence of marked ureteral dilatation in one-third of women who died of cervical carcinoma. This paper provided the stimulus for further investigation into the problem of the changes in the urinary tract which result from cervical malignancy. In the early reports most conclusions were arrived at from autopsy material. This was to be expected for pyelography had as yet not been developed, and surgical technique had not progressed sufficiently to afford the surgeon time to make a careful inspection of the urinary system at the time of the operation.

Williams in 1895 presented in the *British Gynecological Journal* his findings in the autopsies of 78 women who died of advanced cervical cancer. In every case there was evidence of renal disease. In 67 per cent he noted the presence of a gross hydronephrosis and hydroureter. Three-quarters of all patients had demonstrable parametrial involvement by carcinoma. Ewing later concluded from an exhaustive study of the problem that the natural termination of most cases of uterine cancer is through uremia by occlusion of the ureters. Graves and Kickham (6) substantiated this statement by Ewing in a study of 600 autopsies. These authors found evidence of ureteral obstruction in 75 per cent of the material examined. This occlusion of the ureter was brought about by the constricting effect of edema and inflammation and by the direct invasion of the ureteral wall by tumor cells. The same authors (7) in a second similar investigation concluded that 78 per cent of patients with broad ligament involvement from cervical cancer had some demonstrable degree of ureteral occlusion.

During the last 15 years as a result of the ever increasing use of radium and x ray in the

treatment of carcinoma of the cervix the etiology of the changes noted in the urinary tract has become a subject of much debate. Several authorities have suggested that the radiation therapy plays a role in the production of scarring and fibrosis of the juxtavesical portion of the ureter which because of its proximity to the cervix is most vulnerable to the effects of the ray. They are of the opinion that it is this scarring and fibrosis which are responsible for the ureteral narrowing which is noted following therapy. These are the conclusions of Herger and Schreiner, Bugbee and others who definitely place the major blame for the development of the hydronephrosis and hydroureter on therapy rather than on the underlying disease. Everett (3) in 1934 reported the changes in 18 patients 11 of whom developed dense ureteral strictures as a result of radiation therapy or carcinoma of the cervix. In the same paper he cited 2 cases of ureteral stricture which followed radiation for benign conditions. Again in 1939 Everett (4), in an article on the effect of carcinoma on the urinary tract concluded that approximately 50 per cent of the patients treated with x ray and radium for cervical malignancy showed evidence of some constricting lesion involving the lower portion of the ureter.

In reviewing the records of the oncological patients at the University of Maryland we too noted the high incidence of urinary tract disease associated with cervical cancer. From this survey we were unable accurately to determine whether the parametrial spread of the carcinoma, or the effects of the radiation were responsible for the urinary tract changes which developed. It was necessary therefore, to investigate a series of patients with the several grades of cervical cancer and to determine exactly the status of the urinary tract before and after radiation therapy. We felt that only through such a plan could the emphasis be placed on the responsible agent. Thirty seven patients compose this present series, repre-

Read in General Clinical Session, Baltimore Day, Southern Medical Association, Forty-First Annual Meeting, Baltimore, Maryland, November 24-26, 1947.

senting consecutive admissions of new patients with cervical carcinoma to the oncological division of the gynecological department. All patients were treated according to the same plan and all patients have been followed for at least 5 years.

Of the 37 patients comprising this series 31 (84%) were white and 6 (16%) were colored. The youngest was a 25 year old negress with a grade 1 carcinoma, the oldest, a 75 year old white woman with an advanced clinical grade 3 cervical lesion. The average age of the group was 50 years. All patients were married and all but 2 had completed one or more pregnancies. The greatest number of children was 11 and the overall average for the group was 4.

In 11 patients of the group (29%) the carcinoma was confined to the portion of the cervix. Nine patients (24%) had spread of the disease process to the vaginal vaults. The remaining 17 patients (47%) showed unquestionable parametrial involvement and were therefore clas-

sified clinically as grade 3. These statistics suggest that the series, although it was small, represented an average cross section of carcinoma of the cervix.

A detailed history and complete general and special physical examinations were done on the first visit. The carcinoma was graded clinically according to Schmitz. A biopsy of the cervix was taken and a 24 hour report of the tumor made. The microscopic classification used was that of Ewing. The majority of patients in the series received radium therapy before deep x ray. There were only 3 exceptions to this general rule.

We are of the opinion that the technique of radium implantation is a most important factor. For that reason a detailed description of our method is vital to the problem under discussion. Radium implantation at the University of Maryland is an operating room procedure and is generally carried out under sodium pentothal anesthesia. Proctoscopic examina-

tion is done first to rule out the presence of rectal involvement. Following a routine pelvic clean up the patient is carefully examined to determine the pelvic status more accurately. It is this examination under anesthesia that is used in the final clinical grading of the lesion. Thirty milligrams of radium with a 2 millimeter lead equivalent filter are placed in tandem in a flexible rubber sac. This is inserted into the cervical canal. An adhesive tape aluminum foil plaque is made to conform in the size and the shape of the cervical growth. This plaque contains 70 milligrams of radium with a 3 millimeter lead equivalent filter. The tubes of radium are equally spaced by small felt blocks. By this method the distribution of the radiation is entirely uniform. The plaque is introduced in such a manner as to focus the greatest concentration of the ray against the tumor. The bladder and the rectum are protected from radiation by the heavy filters at the extremities of each tube. The plaque is held in place by a large vaginal pack. The pack is inserted meticulously in order to cause the maximum of distention of the vagina. This displaces the cervix and the source of the radiation as far as possible from the bladder and the lower portions of the ureters. The radium is left in place for 30 hours so that a total of 3,000 milligram hours of radiation is given. The same technique is used 3 weeks later to give the second radium treatment. Each patient thereby receives a total of 6,000 milligram hours of radiation. This portion of the therapy is followed in 3 weeks by a course of deep x ray totaling 6,000 to 8,000 roentgen units. All deep x ray is given in divided daily doses through the four standard portals. A second cycle of deep x ray therapy is routinely given 12 weeks later. Throughout all therapy and at regular intervals thereafter all patients are followed by the oncologists.

Before the initiation of any therapy all patients in the series had a complete urological study. This consisted of water cystoscopy at which time a careful inspection of the urethra and bladder were made for evidence of metastatic malignancy, or for the typical cobblestone effect of pressure from an extravesical growth. The ureters were then catheterized with No 6 x ray catheters and complete bac-

Fig. 3. Grade 2 Hydronephrosis and slight hydroneurter before treatment.

teriological studies made of the entire urinary system. A flat film of the abdomen and a retrograde pyelogram were made by the use of 15 per cent skiodan in gum acacia. The pyelogram was made by the gravity method on the side which showed the parametrial involvement or if none was present, on the right side. The contour of the ureter and kidney pelvis was carefully studied and the transverse diameter of the ureter measured at four locations. These measurements were made uniformly at the level of the ischial spine, the lower junction of the ilium and the sacrum, and at the level of the transverse process of the third and fourth lumbar vertebrae. This same urological study was repeated on each patient 1 year after the completion of all therapy and the two constitute the basis of this report.

Twenty patients (54%) of the group gave some initial positive urological history: 15 complained of nocturia, 4 of dysuria, and 1 of questionable hematuria. No patient complained of urinary symptoms following the first radi-

Fig 4 Grade 3 Hydronephrosis before treatment begun.

Fig 5 Grade 2 Hydronephrosis and hydroureter before treatment.

um treatment and only 4 had mild dysuria and frequency as a result of the second. These symptoms were transitory and required only a minimum of medication. Five patients had urological complaints following deep x ray therapy and as before all symptomatology was temporary and none suggested bladder disease.

On cystoscopic examination prior to the initiation of therapy 7 patients (18%) had some degree of demonstrable bladder pathology. Two patients showed a mild cystitis. This apparently was in no way associated with the cervical malignancy. In 3 patients there was evidence of elevation of the bladder floor with the cobblestone effect previously mentioned. All 3 patients had advanced cervical cancer with definite parametrial spread of the disease. The remaining 2 patients showed evidence of early metastatic cancer also associated with a far advanced cervical lesion.

By comparison at the repeat cystoscopic study 1 year later only 2 patients (6.5%) had

bladder pathology. In one patient previously suspected of having metastatic carcinoma the lesion was now quite obvious, and a positive biopsy was obtained. The other patient had developed elevation of the bladder floor. Six patients who originally had some demonstrable bladder lesion showed no evidence of it on the repeat study at the end of the year.

The presentation of a statistical review is at best difficult and at times can be both confusing and boring to the reader. Fortunately this group is small and the points to be discussed are limited to the three major grades of cervical malignancy and the presence or absence of urinary tract pathology.

Of the entire group of 37 patients, 10 (27%) showed some degree of urinary tract dilatation before treatment was instituted. This varied in severity from a very slight hydronephrosis in a patient with an early carcinoma, to an unquestionable hydronephrosis and hydroureter found in 1 of the patients with a grade 3 malignancy. This overall incidence of urinary

Fig 6. Grade 1. Hydronephrosis and hydroureter. No change after treatment. Compare with Figure 3.

Fig 7. Grade 1. Hydronephrosis and hydroureter after treatment. Compare with Figure 1.

tract dilatation is about as would be expected from such a group.

In the series there were 11 patients in whom the cancer was confined to the portio. In 2 of this group (18%) urinary tract dilatation was found. In one patient this was very slight in degree and was limited to the renal pelvis (Fig 1). The second patient showed evidence of a moderate dilatation of both the renal pelvis and the ureter (Fig 2). Of the 9 patients with a grade 2 carcinoma, only 1 showed the presence of demonstrable urinary tract dilatation. This was more marked in the renal pelvis but there was some slight degree of hydroureter associated with it (Fig 3). On examination before treatment, 7 patients (41%) of the 17 with advanced carcinoma and definite parametrial extension showed varying degrees of hydronephrosis and hydroureter. In 3 these changes were confined to the kidney pelvis (Fig 4). The remaining 4 patients showed evidence of both a hydronephrosis and hydroureter (Fig 5).

These findings substantiate the belief that the advanced carcinomas with definite parametrial spread are most prone to be associated with urinary tract dilatations.

One year following the completion of all therapy, each patient was again completely studied and the same urological determinations were done. A meticulous comparison was made of the retrograde pyelograms and the difference carefully noted.

Originally before therapy had been instituted, 2 patients with grade 1 carcinoma had shown dilatation of the urinary tract. The patient in whom a moderate hydronephrosis and hydroureter had been found exhibited no change at the time of the repeat urological study (Fig 6). This patient is living and well more than 7 years after therapy and has continued free of urinary symptoms. The patient who had shown evidence of a slight dilatation confined to the renal pelvis, proved on repeat examination to have a dilatation of both the kidney pelvis and the ureter (Fig 7). Asso-

Fig 9. Grade 2. If dronophrosis and slight hydroureter. Slight increase after treatment. Compare with Fig. 3.

ciated with this change there was a marked extension of the original carcinoma. Two years later the patient died either of tuberculosis or pulmonary metastasis. Unfortunately no autopsy could be obtained. It is of great significance that no patient with a carcinoma grade 1 developed a dilatation of the urinary tract between examinations.

In the group of patients with grade 2 carcinoma of the cervix one had demonstrable urinary tract changes before therapy. Repeat examination revealed only a slight increase in the degree of dilatation (Fig 8). Shortly thereafter the patient developed definite pelvic metastasis, for which a third cycle of deep x-ray therapy was given. The patient has remained in *status quo* is living and is free of urological symptoms. Again it is of significance that no patient with a grade 2 carcinoma developed demonstrable urinary tract changes during the time between examinations.

Of the 17 patients with advanced grade 3 carcinoma, 7 originally had urinary tract dilata-

tion. Six of these showed no appreciable change in the time between examinations (Figs. 9 a and b). Four of the group are living, and well and all are survivals of 5 years or more. Two patients of the original 7 died, one of advanced carcinoma the other of a cerebral accident. One patient with a grade 3 carcinoma had an increase in the degree of dilatation of the urinary tract. This change was confined to the kidney pelvis and no increase in the diameter of the ureter could be demonstrated. In spite of therapy there was a definite spread of the malignant process, and the patient died 2 years later of carcinomatosis.

In contrast to the patients with grades 1 and 2 carcinoma none of whom developed urinary tract dilatation there were 4 with advanced grade 3 malignancy who at the end of the year exhibited changes which had not been present previously. Two of the 4 patients had definite hydroureter and hydronephrosis (Figs. 10 a and b). These patients have subsequently died in uremic convulsions. In the third patient the dilatation of the pelvis of the kidney was obvious but there was question as to any change in the size of the ureter. This patient died of carcinomatosis. The fourth patient to develop urinary tract pathology in the time between examinations revealed only a moderate dilatation confined to the kidney pelvis. This patient has remained well and free of all symptoms for more than 5 years.

In retrospect we had found that before the initiation of any therapy 27 per cent of the entire group had shown some degree of urinary tract dilatation. Seventy five per cent of those who did show these changes had demonstrable parametrial extension of the disease. By comparison at the end of the survey period 38 per cent of the patients showed some degree of hydronephrosis or hydroureter. At this time 79 per cent of those having dilatations also had extension of the malignancy.

We were impressed by the consistency with which we found the association of urinary tract dilatations and extension of the cervical cancer into the parametrial tissues. A second fact was apparent from this survey and one which we felt must be taken into consideration in the final analysis. Patients who had grade 3 carcinoma of the cervix were the only ones to de-

Fig. 9. a, left, Grade 3. Hydronephrosis and slight hydroureter before treatment. b, No change after treatment. Compare with a.

velop urinary tract dilatations during the time between examinations. And furthermore all patients who exhibited an increase in the hydronephrosis and hydroureter showed a definite spread of the disease in spite of therapy and subsequently died of the malignancy (Table I).

It has been established that scarring and fibrosis are the end results of radiation. This is true of normal and malignant tissue. If the ureter in its course through the pelvis were to receive sufficient radiation to bring about scarring and fibrosis then eventually a stricture would develop at that point of the ureter. This stricture in time would produce dilatation of the upper urinary tract. This is the basis of Everett's (4) belief he had maintained that in time half of the patients treated by γ radiation for cervical cancer will develop some degree of ureteral stricture.

The effect of radiation is directly proportioned to the dose and time, and inversely proportioned to the distance from the source of

the ray. Obviously therefore if we were to eliminate stricture effect from radiation as a cause of the urinary tract changes we had to determine the exact course of the ureter through the pelvis. In addition we had to estimate the exact amount of radiation delivered to all points on the ureter by our particular technique of therapy. Finally we had to know the minimal dose of radiation required to bring about these stenosing effects.

The anatomic position of the pelvic ureter is not constant. The course of the right and left ureter differs quite markedly as a result of the presence of the sigmoid and rectum. However the pars intermedia of the pelvic ureter that portion within Mackenrodt's ligament, is similar on either side. It is through this area that the ureter lies closest to the cervix where for a short distance it is from 1.5 to 2.5 centimeters lateral to the cervix (1). However this distance is altered greatly by the position of the vessels, mostly veins, which surround the ureter on all sides. As the veins from the lower

Fig. 8. Grade 1 hydronephrosis and slight hydroureter. Slight increase after treatment. Compare with Fig. 3.

ciated with this change there was a marked extension of the original carcinoma. Two years later the patient died either of tuberculosis or pulmonary metastasis. Unfortunately no autopsy could be obtained. It is of great significance that no patient with a carcinoma grade 1 developed a dilatation of the urinary tract between examinations.

In the group of patients with grade 2 carcinoma of the cervix one had demonstrable urinary tract changes before therapy. Repeat examination revealed only a slight increase in the degree of dilatation (Fig. 8). Shortly thereafter the patient developed definite pelvic metastasis for which a third cycle of deep x-ray therapy was given. The patient has remained in *status quo* is living and is free of urological symptoms. Again it is of significance that no patient with a grade 2 carcinoma developed demonstrable urinary tract changes during the time between examinations.

Of the 17 patients with advanced grade 3 carcinoma 7 originally had urinary tract dilata-

tation. Six of these showed no appreciable change in the time between examinations (Figs. 9a and b). Four of the group are living and well and all are survivals of 5 years or more. Two patients of the original 7 died: one of advanced carcinoma, the other of a cerebral accident. One patient with a grade 3 carcinoma had an increase in the degree of dilatation of the urinary tract. This change was confined to the kidney pelvis and no increase in the diameter of the ureter could be demonstrated. In spite of therapy there was a definite spread of the malignant process and the patient died 2 years later of carcinomatosis.

In contrast to the patients with grades 1 and 2 carcinoma, none of whom developed urinary tract dilatation, there were 4 with advanced grade 3 malignancy who at the end of the year exhibited changes which had not been present previously. Two of the 4 patients had definite hydroureter and hydronephrosis (Figs. 10a and b). These patients have subsequently died in uremic convulsions. In the third patient the dilatation of the pelvis of the kidney was obvious but there was question as to any change in the size of the ureter. This patient died of carcinomatosis. The fourth patient to develop urinary tract pathology in the time between examinations revealed only a moderate dilatation confined to the kidney pelvis. This patient has remained well and free of all symptoms for more than 3 years.

In retrospect we had found that before the initiation of any therapy 27 per cent of the entire group had shown some degree of urinary tract dilatation. Seventy-five per cent of those who did show these changes had demonstrable parametrial extension of the disease. By comparison at the end of the survey period 38 per cent of the patients showed some degree of hydronephrosis or hydroureter. At this time 79 per cent of those having dilatations also had extension of the malignancy.

We were impressed by the consistency with which we found the association of urinary tract dilatations and extension of the cervical cancer into the parametrial tissues. A second fact was apparent from this survey, and one which we felt must be taken into consideration in the final analysis. Patients who had grade 3 carcinoma of the cervix were the only ones to de-

Having determined the relative position of the ureters to the source of the ray we next had to learn the amount of radiation delivered to the various portions of the pelvic ureter by our particular method of radium implantation. For this we turned to the work of A. N. Aronson who among others had estimated the distribution of radiation within the average female pelvis. His measurements for the size of the bony pelvis and the viscera were taken from the work of Davis and Williams. Following his technique we plotted the isodose curves of radiation delivered within the pelvis by our method of therapy. Superimposing on these curves the various positions of the ureters as determined by our cystoscopic studies the authors have been able to estimate the dosage of radiation to all portions of the pelvic ureter. From this study we have concluded that at no point in its course through the average pelvis is the ureter subjected to more than 35 to 45 milligram hours of exposure. In those patients in whom the maximum effectiveness of the vaginal packing was obtained the dosage was appreciably less. These patients received as little as 18 to 25 milligram hours of radiation.

Fig. 11. Radium filters before vaginal packing.

uterus and upper vagina anastomose they lie medially and tend to displace the ureter laterally toward the pelvic wall. On its exit from Mackenrodt's ligament the ureter diverges rapidly and enters the bladder obliquely about 15 centimeters below the level of the anterior cervical lip. Most important of all is the fact that the ureter in its course through these areas is held firmly in place by the surrounding vessels and the connective tissue framework.

Upward traction on the uterus increases the distance between the cervix and the ureters a great asset in doing a total hysterectomy from above. If this were not true injury to the ureter as it transverges the ligament of Mackenrodt would be a much more common occurrence. In radiation work the maximum accurate packing of the vagina accomplishes this same effect namely to push the uterus and cervix upward and backward away from the ureters fixed in their beds. On this we believe depends the successful protection of the ureters from the effects of radiation.

To determine accurately the change of distance before and after vaginal packing we have made measurements on operative and autopsy material and on normal patients in the cystoscopic clinic. In the latter group we first passed x ray catheters into the right and left ureters. Using radium filters we made a plaque similar in size to one used in therapeutic application. This was placed against the cervix and a flat film of the abdomen was taken (Fig. 11). The vagina was then carefully packed in the routine manner and a second roentgenogram was taken (Fig. 12). Measurements were made of the change in distance between the ureters and the cervical plaque before and after packing. In the average case we were able to push the uterus and cervix upward and backward toward the promontory of the sacrum so that the distance of the source of radiation from the most vulnerable portion of the ureter was increased by about 5.5 centimeters. In patients obtaining the most effective packing this increase was as much as 8.5 centimeters.

malignancy and has invariably proved to be a grave prognostic sign

3 The majority of patients with carcinoma grades 1 and 2 did not show changes in the urinary tract before therapy, and none of the patients in these groups developed a dilatation during the period of time between examinations.

4 Urological studies of all patients who have cervical carcinoma are indispensable for purposes of intelligent evaluation and management.

5 Radiation therapy will not cause stricture of the ureter if the dosage is not excessive and provided the source of the ray is displaced from the ureter by accurate maximal vaginal packing

b, Radium filters, after packing. Lateral view

From these studies we had been able to determine with some degree of accuracy the amount of radiation given to the most vulnerable portion of the ureter. Knowing this dosage we had only to compare it with the amount of exposure needed to cause stenosis of the ureter.

The majority of this work has been carried out in laboratory animals. Martin and Rogers in their work on dogs found that 100 milligram hours of radiation to the abdominal portion of the ureter resulted in a complete stenosis. By back pressure this subsequently caused a hydronephrosis and hydroureter. Doses of less than 50 milligram hours of radiation produced very little if any effect. Demonstrable changes were not noted until after the ureter had been exposed to 75 or more milligram hours of radiation.

A correlation of these studies leads to the conclusion that even with inadequate vaginal packing our method of cervical radiation definitely delivers less than the minimal amount necessary to produce stenosis of the ureter.

These results are in keeping with our clinical studies in which we found that in patients

without extension of the cervical carcinoma into the parametrial tissue a stenosis of the ureter did not develop during the time between the two urological studies. Objection might well be raised on the basis that the 1 year period of time was not sufficient to produce the stenosis necessary for the eventual development of a hydronephrosis or hydroureter. We can best answer this objection by saying again that by our particular method of radium implantation and vaginal packing as previously described even the most vulnerable portion of the ureter receives considerably less than the minimal amount of radiation necessary to cause stenosis.

CONCLUSIONS

From these studies we have arrived at the following conclusions:

1. The more advanced the original cervical carcinoma the more frequent is the association of urinary tract dilatation before the initiation of radiation therapy.
2. The development of a hydronephrosis and hydroureter during or after treatment has in every case been associated with advancing

Fig. 1. Drawing of the steps in repair of a defect in the anal sphincter. Upper left, Note the location of the incision and the sulcus in the scar at the site of the defect. Upper right, The steel sutures have been laid and drawn up. The "pull-out" sutures are indicated by arrows. Note how the concentric incision has become radial and the present position of points B and B'. The sulcus has disappeared and is replaced by an invaginating elevation. The lower drawings are detailed cross sections to clarify the method of placing the retention sutures. Note that they are in scar tissue and that the two ends of each "pull-out" suture emerge through a single opening in the skin. Gauze should be placed between the buttons and the skin to prevent erosion.

retention sutures. Smiley has reported good results from the use of steel alloy wire as retention suture material in sphincter repair as has Kallett who also used this method.

Some of the reasons for failure in attempted sphincter repair are the following: (1) There is a high incidence of wound infection with subsequent dehiscence of the wound. This location is obviously of high potentiality for contamination from the nearby fecal outlet. (2) When large retention sutures are used particularly when placed so that strangulation of tissue occurs a necrotic nidus of infection is formed. Retention sutures that have been described previously are almost inevitably strangulating. (3) Catgut absorbability is rapid in the presence of infection. When it is used as suture material its holding strength is lost before the opposed structures are able to maintain union and separation occurs. (4) The sulcus in the scar between the divided muscle ends as mentioned previously remains after some types of repair. This results in contamination of the close-by operative wound during

the immediate postoperative period of healing as well as in continued leakage or partial incontinence. (5) In the 'classical' repair sutures are placed in poorly holding muscle and may not appose the dissected edges for a sufficient period of time for them to unite firmly. Further the trauma imposed upon the muscle in the course of the operation results in further extension of cicatrization in the muscle.

The method to be described below is based upon Bunnell's principle of "suturing at a distance" with steel alloy wire which he has evolved in the repair and reconstruction of tendons. It has other features which tend to overcome some of the factors in failure enumerated above. No. 34 steel alloy wire is employed. This has a diameter of 0.006 inch and is comparable in strength to a size in silk one half diameter greater. It breaks at 7 pounds tension. For greater strength No. 30 or even No. 28 may be used. Its tensile strength is high; it ties smoothly and engenders a minimal tissue reaction. It should never be allowed to **link**.

A METHOD OF REPAIR FOR A COMMON TYPE OF TRAUMATIC INCONTINENCE OF THE ANAL SPHINCTER

WALTER BIRNBAUM M.D. F.A.C.S. San Francisco, California

AMONG the traumatic causes of Incontinence of the anal sphincter are accidental injuries obstetrical injuries operations in the anorectal region and irreparable dilatation of the anorectal sphincteric apparatus. The majority of cases of fecal incontinence occur after anorectal fistulectomy and are usually due to improper or too extensive incision of the anorectal ring or to the pernicious practice of postoperative packing. However, a considerable number follow simple incision of an abscess or an otherwise uncomplicated hemorrhoidectomy. The greatest number of defects occur in the lateral quadrants although contrary to common belief in many instances the defect is directly posterior.

The term sphincter mechanism is used advisedly to indicate a more complex structure and action than are comprised by merely the internal and external sphincters commonly mentioned when the anorectal ring is referred to. A clear conception of the anatomic components of the anorectal ring is essential for the surgeon undertaking operative procedures in this region or attempting repair of the already injured muscle.

The extent of injury leading to incontinence may vary from a segmental one to complete destruction or absence of the muscle. The method of repair to be described here deals only with those in which a relatively small segment is lost although it may be modified to apply to larger defects.

Two factors are involved in the mechanism of incontinence. (1) Because of an actual increase in the circumference of the anus the muscle when it contracts, is unable to close the orifice. The interposition of a noncontractile and fixed scar abets the failure of complete closure. (2) Scar tissue in the muscle creates a sulcus interrupting the normal contour of the anal periphery. Because of the puckering

action of the ovoid-shaped elements of the sphincters the anus is normally corrugated, with elevations and depressions alternating about its circumference. When a portion of the muscle is replaced by a scar the epithelium covering it forms a smooth trough through which there is an escape of feces and secretion. This sulcus if not removed may also be the source of contamination of an operative wound external to it.

Many types of repair of the incontinent sphincter have been offered some of which appear to have met with a gratifying degree of success. Many failures are reported however with most of the methods employed. The so-called classical repair is probably the most widely used, although the literature is not fruitful in reports of its success and the consensus of those who have employed it is not wholly favorable. This method consists in dissecting out the scar tissue and reapposing the retracted muscle ends. Buile has found that in those instances in which packing after fistulectomy has resulted in a wide scar separating the muscle ends simple excision of the cicatrix is sufficient to correct the defect. The muscle need not be reapposed by suture. Blaisdell has developed an ingenious method in which through an anterior incision the muscle is reefed in such a manner that the circumference of the sphincters is decreased. Other procedures are based upon reflection of a section of the anococcygeal portion of the superficial fasciculus of the external sphincter and muscle. For large defects fascial strips which encircle the canal and are sutured to the edges of the gluteal muscles have been described by Wreden Stone, and McLanahan. The scarred muscle ends may be apposed through a semilunar incision concentric with the anus. This method described by Blaisdell has the distinct advantages of simplicity and of suturing through a scar with high tissue tension. Annular pursestring sutures have been used as

Fig. 1. Drawing of the steps in repair of a defect in the anal sphincter. Upper left, Note the location of the incision and the sulcus in the scar at the site of the defect. Upper right, The steel sutures have been laid and drawn up. The "pull-out" sutures are indicated by arrows. Note how the concentric incision has become radial and the present position of points B and B'. The sulcus has disappeared and is replaced by an invaginating elevation. The lower drawings are detailed cross sections to clarify the method of placing the retention sutures. Note that they are in scar tissue and that the two ends of each "pull-out" suture emerge through a single opening in the skin. Gaze should be placed between the buttons and the skin to prevent erosion.

retention sutures. Smiley has reported good results from the use of steel alloy wire as retention suture material in sphincter repair as has Kallett, who also used this method.

Some of the reasons for failure in attempted sphincter repair are the following: (1) There is a high incidence of wound infection with subsequent dehiscence of the wound. This location is obviously of high potentiality for contamination from the nearby fecal outlet. (2) When large retention sutures are used particularly when placed so that strangulation of tissue occurs, a necrotic nidus of infection is formed. Retention sutures that have been described previously are almost inevitably strangulating. (3) Catgut absorbability is rapid in the presence of infection. When it is used as suture material its holding strength is lost before the opposed structures are able to maintain union and separation occurs. (4) The sulcus in the scar between the divided muscle ends as mentioned previously remains after some types of repair. This results in contamination of the close by operative wound during

the immediate postoperative period of healing as well as in continued leakage or partial incontinence. (5) In the classical repair sutures are placed in poorly holding muscle and may not appose the dissected edges for a sufficient period of time for them to unite firmly. Further, the trauma imposed upon the muscle in the course of the operation results in further extension of cicatrization in the muscle.

The method to be described below is based upon Bunnell's principle of "suturing at a distance" with steel alloy wire, which he has evolved in the repair and reconstruction of tendons. It has other features which tend to overcome some of the factors in failure enumerated above. No. 34 steel alloy wire is employed. This has a diameter of 0.006 inch and is comparable in strength to a size in silk one-half diameter greater. It breaks at 7 pounds tension. For greater strength No. 30 or even No. 28 may be used. Its tensile strength is high; it ties smoothly and engenders a minimal tissue reaction. It should never be allowed to kink.

Fig. Diagram 1. Illustrate the direction of pull of the retention sutures.

The patient is prepared preoperatively with oral administration of nonabsorbable sulfa drugs cleansing enemas, and a nonresidual diet. Transsacral anesthesia is preferable. The prone jack knife position is used. The anal canal is packed with an antiseptic saturated gauze and carefully draped out of the operative field. Atraumatic aseptic technique is observed. A crescentic incision just lateral to and centered over the defect is made and carried down to the required level. Excessive scar is removed en bloc. The dissection is not carried back to normal muscle but rather the muscle ends are allowed to retain enough scar so that sutures may be firmly placed in scar tissue. It must be borne in mind at this point that the entire defect in the anorectal ring which may include the levator and the longitudinal muscle of the rectum the internal sphincter and the two deeper bundles of the external sphincter must be identified.

The steel wires are then laid as shown in Figure 1 being passed through the loop of the pull-out wire. Note in Figure 2 that the direction of pull is tangential to the circumference of the muscle i.e. the end of the muscle to be apposed is held in direct line with its fellow which is, in turn, fixed in the same manner. The 'pull-out' suture (illustrated in Fig. 1) is looped through the end of the holding suture and brought out through the skin with

both of its ends threaded through the eye of a single needle. Thus, both ends of the "pull-out" suture emerge through a single opening in the skin. The steel sutures are then drawn up sufficiently to convert the longitudinal wound into a transverse one, and the defect is closed in layers without tension. The author prefers the use of fine interrupted cotton sutures. The retention sutures are secured to the surface of the skin with buttons and tightened. Several layers of gauze are placed under the buttons to avoid pressure ischemia of the skin. When the operation is completed it will be observed that the longitudinal wound has been converted into a transverse one and that the sulcus referred to becomes a fold invaginating itself into the anus. Thus the normal corrugations of the anus are restored. No bowel movement is permitted for at least 7 days. The sutures are removed at end of 14 days.

This procedure has been employed upon three occasions with good results.

SUMMARY AND CONCLUSIONS

Failure often follows attempts at repair of the incontinent anal sphincter for a variety of reasons.

A method of repair is described which requires minimal dissection, converts the ditch-like defect into an elevation simulating the normal contour of the anus, obviates strangulating retention sutures and provides sufficient suture traction in the proper direction.

TUBERCULOSIS OF THE CERVICAL LYMPH NODES

The Present Surgical Status

CHARLES W LESTER, M D., F.A.C.S New York, New York

TUBERCULOSIS of the cervical lymph nodes was a common disorder of childhood until about 1920 and its surgical treatment was firmly established. Dowd who wrote extensively on the subject reported nearly 700 personal cases in 1916. Shortly thereafter the incidence began to decrease so that Hanford in 1933 could report on but 131 cases treated surgically. In England there was still a considerable number of cases and up to the time of the war the arguments for and against surgical treatment of tuberculous cervical lymphadenitis were published in the British literature by Thompson, Barrington Ward, Turner, Franklan, Evans and others.

Certain significant changes have taken place to alter the incidence of this disease since Dowd compiled his series of cases.

First, tuberculosis in dairy herds has almost been eliminated thus removing bovine tuberculosis as a factor. This is often mentioned but it was not a major consideration even in 1906 when Park examined a representative group of Dowd's cases and found that bovine tuberculosis accounted for only about 30 per cent of the cases.

Second, the widespread removal of tonsils and the replacement of the old guillotine operation by enucleation of the tonsils removed an important portal of entry, not only for tuberculosis but also for pyogenic infections which lessen the resistance of the nodes to lymph-borne or hematogenous infection with tuberculosis. As the nodes draining the nasopharynx are usually the first involved this probably has some significance.

Third, the great decrease in tuberculosis generally has vastly diminished the chances for exposure. In 1915 a positive tuberculin test in a child over 2 years of age was not con-

sidered of great significance but in 1948 a positive tuberculin test at any time in childhood has considerable diagnostic weight. This is undoubtedly the most important factor in the decreased incidence of lymph node tuberculosis.

With so few cases encountered it is natural that the good surgical results of other years should be forgotten. Pediatricians (and many surgeons as well) are prone to consider the surgical treatment of accessible tuberculous lymphadenitis as ineffectual, dangerous and disfiguring. For that reason every other form of treatment is tried first and the surgeon called only when a cold abscess is about to rupture. This concept is ridiculous. Surgical treatment, though differing from other neck dissections, can still produce the best results in properly selected cases, particularly if operation is performed before cutaneous sinuses have developed, and operation certainly need not be disfiguring.

Tuberculosis of the cervical lymph nodes may occur at any age but is predominately a disease of childhood. It is not frequently associated with active pulmonary tuberculosis and is present in only about 5 per cent of the patients admitted for tuberculosis to the pediatric tuberculosis division at Bellevue Hospital. Among adult patients the association is even much less. There were but 20 cases among 2,778 admissions for tuberculosis to the adult service at Bellevue in 1945 and at the New York Municipal Sanatorium at Otisville there were only 19 among 3,998 admissions from 1940 to 1948. Nevertheless every case of lymph node tuberculosis should be subjected to a thorough search for tuberculous foci elsewhere. While the nasopharynx may be the portal of entry it is quite probable that the neck nodes draining this area are infected by way of the blood or lymph streams from an infection originating in the lungs which may

From the Children's Surgical Service, Bellevue Hospital, New York.

Fig. Imports anatomical structures in the neck. The marginal mandibular branch of the facial nerve is often a little lower than depicted here. The twelfth cranial nerve usually traverses the sternocleidomastoid muscle. It is exposed in the plot re 1 mark. Its course more evident. The nerves of the cervical plexus are sensory and are cut without danger.

be healed merely deliquescent or possibly active.

The pathology of lymph node tuberculosis need not be recounted. There are several features which should be mentioned however. Lymph node tuberculosis has an acute phase which corresponds to the exudative phase of pulmonary tuberculosis. Fibrous tissue around the nodes perilymphadenitis is a prominent feature of the disease. Liquefaction follows caseation and appears first within the node capsule from which it may rupture into the surrounding tissue to form a cold abscess and thence through the skin to form a sinus.

The clinical diagnosis offers little trouble. A firm swelling in the neck usually starting beneath the angle of the jaw which is tender at first but later painless and tends to extend rather than subside is probably tuberculosis. An acute infection in the same location sub-

sides or suppurates in less than a month. The lymphomas feel more elastic and while they may present a massive swelling give the impression of being more discrete. The congenital cystic structures are stationary do not tend to extend and have typical locations.

Treatment of tuberculous lymphadenitis is determined by a consideration of the clinical and pathological situation in any particular case. In the exudative phase of the disease, while the nodes are tender and the patient toxic, bed rest and all the supportive treatment applied to pulmonary tuberculosis are indicated. This is especially true when the lymph node infection is merely a local manifestation of a systemic disease. To operate at such a time would only activate or accelerate the disease elsewhere and should not be done except in those rare instances in which the lymph node disease is having a deleterious effect on the systemic disease. Ultraviolet radiation, a popular form of treatment at one time, is probably of little real value and may do harm in the presence of a pulmonary lesion.

Röntgen therapy has a wide vogue. Unfortunately it is used in a haphazard fashion without due regard to its limitations but when indicated it is a valuable adjunctive treatment. It cannot destroy the mycobacterium tuberculosis and is in no sense a sterilizing procedure. Nor can it cause the disappearance of a cold abscess or of caseation necrosis. Its chief effect is to produce fibrosis which is the method by which the body combats the infection. It is therefore of value early before caseation necrosis has developed and late when cold abscesses drain through chronic sinuses. Its use should be reserved to these indications and it will then be of great value. To continue irradiation of caseous nodes or of cold abscesses submits the patient to useless irradiation.

Streptomycin has recently come to the fore as a treatment for various types of tuberculosis but little has been written of its use on tuberculous lymph nodes except in a limited number of cases in the government hospitals of the Army, Navy and Veterans Administration. Here the reports are equivocal in that some nodes seemed to get smaller while others were unaffected. In no instance was the dis-

case eliminated. Its use on tuberculous sinuses however, has been strikingly good and most of these have healed under streptomycin therapy.

In considering streptomycin therapy certain facts must be borne in mind. First the drug practically always produced toxic symptoms if given in the original dosage for a time adequate to produce therapeutic results. The smaller dose now employed has eliminated much of this trouble but it is always a possibility. Second when the drug has been given for a variable length of time the organisms in the lesion are found to be streptomycin fast. Whether this is due to the development of resistance in the organism or to the destruction of all the nonresistant strains leaving the resistant strains to take over makes little difference to us. Streptomycin can be used for only one full therapeutic course after which it loses its efficacy. Third the drug is most effective in the acute exudative phase of tuberculosis and of scant value, or none at all in the caseous and fibrotic phases of the disease.

Thus we do not advocate streptomycin as a therapeutic agent in the treatment of tuberculous lymphadenitis. Because caseation and fibrosis are prominent features in the disease streptomycin cannot be expected to produce favorable results. At the same time the use of streptomycin produces resistance in the infecting organism so that it will be without value in the treatment of an acute flare-up of the disease should this ever occur. We do advocate its restricted use as a prophylactic measure with surgery to prevent the spread or activation of the disease elsewhere.

The 12 cases in which we have used streptomycin have been in this category and in 11 of them the result was satisfactory. The 1 patient in whom the result was unfavorable had already had a long course of treatment with streptomycin for mediastinal nodes and was presumably streptomycin resistant. One case was particularly interesting in that the child had quiescent lesions in bones and lungs which would ordinarily interdict operation. With prophylactic streptomycin the mass of broken down nodes in his neck that were retarding his recovery was removed without reactivation of any of the lesions and his improvement

Fig. 2. The common incisions. The lowest is seldom used but if this amount of exposure is necessary it leaves less scar than one along the sternomastoid.

thereafter was rapid. One patient had multiple sinuses outside the area of operation which healed while streptomycin was being given.

In using streptomycin prophylactically our aim is to use enough to prevent reactivation or spread of the lesion but at the same time to avoid toxic symptoms and the production of an organism resistant to the drug. The daily dose of the drug is 10 milligrams per pound of body weight up to 1 gram given in four divided doses. It is started the day before operation and discontinued not later than 2 weeks after operation. If the likelihood of spread seems small it is discontinued on the eighth day after operation. In this way toxic symptoms are avoided and we hope that the organism has not become drug fast. We have not yet had occasion to find out by direct observation.

With all the new modalities for the treatment of accessible tuberculous nodes the treat

ment of choice is still their *complete* removal in properly *selected* cases. Dowd and Hanford have shown this in the past and it is just as true today. Anything less than complete removal is inadequate. Aspiration or drainage of a cold abscess even with curettage of the caseous node is not complete removal. Careful selection is also essential. Operation in the acute phase is not to be considered any more than operation for pulmonary tuberculosis while the lesion is exudative. Nor is operation to be considered when the nodes are only the local manifestation of a systemic infection. To operate in such a situation is both futile and dangerous. Therefore every case must be studied by x ray, blood count and sedimentation rate and by any other means necessary to rule out active lesions elsewhere.

The ideal time for operation is while the nodes are still relatively discrete. The formation of a cold abscess in the tissues around the nodes adds to the difficulty and the formation of a cutaneous sinus further complicates the situation. In neither instance is operation contraindicated provided the other conditions are favorable.

One of the objections raised to the surgical treatment of cervical lymphadenitis is the possibility of damage to important structures in the neck chiefly the motor nerves. This is much more apt to happen in the presence of cold abscesses but can be avoided even then. For that reason it is important that the surgeon familiarize himself with the important anatomical structures in the neck, especially the marginal mandibular branch of the seventh nerve and the eleventh nerve. Figure 1 shows these structures.

The marginal mandibular branch of the seventh nerve crosses the angle of the mandible and lies just caudad to it as far as the facial vessels where it ascends onto the face. It lies beneath the platysma and on the deep cervical fascia. An incision a finger's breadth beneath the mandible will avoid it and if it is necessary to dissect upward the dissection must hug the capsule of the node. If injured it paralyzes the quadratus labii inferioris and interferes with puckering the mouth or smiling.

The eleventh nerve leaves the skull through the jugular foramen crosses the transverse

process of the atlas under the posterior belly of the digastric, and enters the upper third of the sternomastoid muscle to emerge at about the middle of the posterior border to supply the trapezius. It can be injured anywhere along its course. The landmark to use is the transverse process of the atlas and great care should be used when dissecting under the sternomastoid in this region. Nodes frequently surround it and every structure should be identified before it is severed. The nerve is fairly large and with care should always be identified.

The internal jugular vein is frequently surrounded by diseased nodes which must be dissected from it. The vein may be damaged but usually brisk venous bleeding comes from a tributary severed near the jugular vein and not the vein itself. This type of bleeding can be controlled by temporary packing. If the internal jugular vein is damaged it does no harm to ligate it.

Ether is the anesthetic agent of choice administered through a nasal catheter or pharyngeal tube. This allows the anesthesiologist to keep out of the way. The use of a tube within the trachea is to be avoided. The trachea of a child is small and the manipulation of the surgeon in dissecting the nodes in the vicinity causes the tube to traumatize the trachea. Tracheitis is usual after the use of the endotracheal tube and in one of our patients tracheotomy was necessary.

Incisions should be made in or parallel to natural creases of the neck as shown in Figure 2. Longitudinal incisions heal with a broad scar which is unsightly. They are seldom necessary but should they be they are best made by extending a transverse incision upward next to the hair line as shown. The scar is less noticeable in this place. If a cutaneous sinus is present it should be excised in one of the standard incisions.

It should be stressed that the cardinal principle in the operation for the removal of tuberculous cervical nodes is the complete removal of all the diseased nodes. There is always much perilymphadenitis present which can effectually hide many diseased nodes. Before terminating the operation careful search should be made for these by palpation and by

direct vision. This cannot be emphasized too strongly. The removal of tuberculous cervical lymph nodes is a slow and tedious process requiring the time and patience to do a thorough job. It is not an operation to be turned over to an inexperienced resident without careful supervision. Diseased nodes left behind enlarge rather promptly and necessitate a secondary operation for their removal. A certain number of secondary operations are unavoidable but most of them can be prevented by careful removal of the nodes at the time of the original operation.

After the incision has been made as described it is deepened down through the platysma to the node. The fibrous tissue around the node is densely adherent to the capsule and tends to obliterate the cleavage plane which must be defined by sharp dissection. To obtain the proper exposure the node must be grasped in Kocher or in Lahey goiter clamps. More traction must be exerted than will permit the use of an Allis clamp. In dissecting the nodes out we prefer modified curved Mayo scissors with thin narrow tips. The dissection is kept well up on the node as close to it as possible and the adhesions are spread with the scissors and then snipped. This requires sharp scissors which cut to the end (Fig. 3).

Traction on the mass should be relaxed frequently and the adjacent tissues carefully inspected for blood vessels and nerves. Tension empties the veins and makes them indistinguishable until they are cut and bleed (Fig. 3 h and c) and nerves under tension look like fibrous tissue. After working in one direction for some time the operator may find that he is in a deep recess where exposure is poor. The mass should then be attacked from an other direction which will make it easier to identify important structures and to maintain orientation.

Cold abscesses are frequently encountered and contamination of the wound by tuberculous pus is of no consequence. If the cold abscess is confined to the node the dissection can be carried on without regard to it. If the cold abscess is in the tissues the wall of the cold abscess must be excised as well as the underlying nodes which are responsible for it. This is a difficult procedure during which in-

Fig. 3. Technique of lymph node dissection. A The adhesions to the node are divided well up on the node. B Traction exposing the adhesions but also hiding a large vessel which becomes apparent when the traction is released as in C.

jury to the nerves and blood vessels can easily occur. If there is a draining cutaneous sinus the same surgical principle holds. With the use of penicillin most of these wounds heal promptly.

The wound is closed by suturing the platysma first and then the skin. We usually place a small piece of rubber dam or a seton of silkworm gut in the wound to take care of the fluid forming in the dead space. This is removed the first day after operation and fluid which collects after that is removed by aspiration through normal skin. The wound should never be probed or otherwise opened unless there is frank pyogenic infection. The patient is allowed out of bed the day after operation, the sutures are removed on the fifth day and the patient discharged the following day.

Complications are chiefly those which have to do with injury to one of the motor nerves and the marginal mandibular branch of the

seventh nerve is the one most commonly injured. When the nerve traverses the wall of a cold abscess it is hard to identify. In such a case it is better to leave part of the wall and trust to streptomycin to heal the wound. Most of the injuries to the seventh nerve are caused by too vigorous retraction and such injuries are of only short duration.

Sinuses and recurrences are complications resulting from incomplete removal of the diseased nodes. Most of them can be avoided by careful surgery but the complications are sure to occur now and then. Recurrent nodes should be operated upon again. Sinuses result from caseous material in the wound usually an overlooked node. The node should be removed but if it is not apparent x ray therapy or streptomycin are potent agents in closing sinuses. Sinuses due to a mixed infection should have penicillin treatment as well. An acute activation of tuberculosis following operation for tuberculous lymph nodes means that an active focus was overlooked before operation. It should never happen.

Results have been uniformly good. Some patients have had to be operated upon again and we have had to use x ray therapy to close an occasional sinus. The antibiotics give us a great advantage which was denied to the older surgeons and if the disease is not allowed to drag on too long before coming to opera-

tion our results should be much better than theirs. This will happen when the advantages of surgical treatment are as well recognized as they were 30 years ago.

SUMMARY

1. Tuberculosis of the cervical lymph nodes is much less common than it was in an earlier generation and its character has changed.

2. Surgical removal of the involved nodes is the most satisfactory form of treatment. General hygienic measures and x ray therapy are valuable adjuvants.

3. The judicious use of streptomycin is promising.

THE SURGICAL ANATOMY OF CYSTOCELE AND URETHROCELE WITH SPECIAL REFERENCE TO THE PUBOCERVICAL FASCIA

BYRON H GOFF M.D., F.A.C.S. New York, New York

A LARGE majority of gynecologists and general surgeons believe that there is in the human female pelvis a layer of closely felted fascia which it is alleged is attached to the posterior surface of the body of the os pubis along its lower border and to the cervix uteri a short distance above the external os. Some contend that this layer of fascia is situated just beneath the vaginal mucosa and that it surrounds the vagina while others believe that it separates the vaginal wall from the walls of the bladder and the urethra and that it extends laterally to become continuous with the fascia endopelvina. This layer of fascia has been termed the pubocervical fascia. Synonymous terms are pubouterine fascia, pubovesicocervical fascia and musculo-fascia.

The group who believe that the pubocervical fascia is an anatomic entity contend that a congenital defect in it or an obstetric injury to it is the basic cause of cystocele and urethrocele. They reason logically therefore that a successful surgical correction of a cystocele or urethrocele depends upon the reconstruction of the defective or damaged part of the pubocervical fascia. It is important to keep clearly in mind the fact that such a concept of the etiology and surgical correction of cystocele and urethrocele is based entirely upon empiric observations made during operations on the living subject or gross dissections on the cadaver.

In view of the fact that authoritative anatomists do not mention the pubocervical fascia and that a considerable number of gynecologists are completely convinced that there is no such fascia in the human pelvis it is important to review the anatomic and histologic facts upon which their conviction is based. It is

obvious that it is possible to form a clear concept of the etiology of cystocele and urethrocele and of the histologic character of the tissues involved in their surgical correction only upon such facts.

To correlate the evidence against the existence of the pubocervical fascia it is necessary to consider (1) the attachments of the vagina, the urinary bladder and the urethra, (2) the histology of the normal vaginal bladder and urethral walls and (3) the normal vesicovaginal and urethrovaginal septa.

THE ATTACHMENTS OF THE VAGINA

The vagina is attached at its upper extremity to the cervix uteri a short distance above the external os. The muscular coat of the vaginal wall blends with the musculature of the cervix and its mucosa is continuous with the mucosa of the portio. At its lower extremity the vagina penetrates and is attached to the urogenital trigone by its muscular coat. The vaginal mucosa and the mucosa of the introitus are continuous. The anterior vaginal wall above the urogenital trigone fuses so intimately with the posterior urethral wall that there is no line of normal cleavage between them. At a higher level the anterior vaginal wall is loosely attached to the wall of the bladder by a delicate layer of areolar connective tissue which marks a line of natural cleavage between the muscular coat of the vaginal wall and the muscular coat of the bladder wall. The posterior vaginal wall above the urogenital trigone fuses with the upper part of the wall of the anal canal and at a higher level it is attached to the anterior rectal wall by a delicate layer of areolar connective tissue which marks a line of normal cleavage between the muscular coat of the vaginal wall and the muscular coat of the rectal wall. Laterally the vaginal walls are attached to the visceral part of the

From the Department of Obstetrics and Gynecology, Cornell University Medical College, and the New York Hospital.

Fig. 1. The urethra and vagina penetrate and are attached to the urogenital triangle below the os pubis. Any layer of fascia which might traverse the length of the anterior vaginal wall or separate the vaginal wall from the wall of the urethra and the bladder would have to be attached at its lower extremity to the urogenital triangle. The term perineal fascia, which indicates an attachment of the fascia to the pubic bone, is inaccurate.

fascia endopelvina which is continuous with the vesicovaginal and rectovaginal areolar connective tissue.

THE ATTACHMENTS OF THE BLADDER

The ligaments of the bladder are described as true and false, under the latter being included the peritoneal folds that pass from the organ to the adjacent abdominal and pelvic walls. From the manifest instability of relations and attachments of the peritoneum incident to distention and contraction it is evident that such peritoneal folds can contribute little to the definite support or fixation of the bladder; hence those parts of the organ possessing a serous covering are movable. The inferior surface on the contrary is comparatively fixed on account of its close relations to the pelvic floor and the presence of *true ligaments*. These are derived from the pelvic fascia which in the vicinity of the bladder presents a stout, glistening band-like thickening (arcus tendineus) that on each side

Fig. 2. Lateral view of the pelvis showing the lateral ligaments and the penetration of the urogenital triangle by the urethra and vagina below the pubic bone.

stretches from the posterior surface of the symphysis, a short distance above its lower border backward to the ischial spines. On either side of the midline the anterior ends of these tendinous arches pass as strong fascial bands from the symphysis to the bladder as *anterior true ligaments*. After leaving the symphysis the tendinous arches send expansions—the *lateral true ligaments* to the sides of the bladder (Piersol). The posteroinferior surface of the bladder is loosely attached to the vaginal wall and to the uterus by a delicate layer of areolar connective tissue.

THE ATTACHMENTS OF THE URETHRA

At its upper extremity the urethra penetrates the wall of the bladder and its muscular coat blends with the musculature of the bladder wall. At its lower extremity the urethra penetrates and is attached to the urogenital triangle by its muscular coat. The urethral mucosa blends with the vesical mucosa and that of the introitus. The anterior urethral wall is attached to the connective tissue in the floor of the space of Retzius. The posterior urethral wall above the urogenital triangle is intimately attached to the anterior vaginal wall. Laterally the urethral wall is attached to the fascia endopelvina.

With the attachments of the walls of the vagina, bladder and urethra clearly in mind

Fig. 3 Longitudinal section of the normal vaginal wall. 1 Vaginal epithelium 2 tunica propria of vaginal mucosa 3 papilla 4 internal circular muscle layer 5 external longitudinal muscle layer 6 fibrous layer 7 interstitial connective tissue 8, artery in muscle 9 ganglion 10, fat lobules. it is apparent that any layer of fascia which might traverse the full length of the vaginal wall or which might separate the vaginal wall from the walls of the bladder and urethra would have to be attached at its lower extremity to the urogenital trigone below the pubic bone (Figs 1 and 2). It is obvious therefore

Fig. 5 Longitudinal section of normal urethral wall. 1 Urethral epithelium 2 urethral glands 3 tunica propria of urethral mucosa 4, longitudinal muscular layer 5 circular muscular layer (From Pierol.)

Fig. 6 Horizontal section of the anterior wall of the bladder and the cervix of the vagina. 1. Epithelium of the bladder; 2. Mucosa of the bladder; 3. Circular muscular layer of the bladder wall; 4. that the term pubocervical fascia which undoubtedly indicates an attachment to the pelvic bone is inaccurate. In behalf of accuracy in the teaching of vaginal plastic surgery it is important to eliminate the term pubocervical fascia and its synonyms from gynecological nomenclature.

HISTOLOGY OF THE NORMAL VAGINAL WALL

The normal vaginal wall (Fig. 3) from 2 to 3 millimeters thick, includes a *mucous* and a *muscular coat* supplemented externally by an indefinite *fibrous coat*.

The mucous coat consists of a fibroelastic tunica propria exceptionally rich in elastic fibers and veins, the inner surface of which is beset with numerous conical papillae that encroach upon the overlying epithelium but do not model the free surface. The epithelium from 0.15 to 0.20 millimeter thick is stratified squamous in type.

The muscular coat which directly supports the mucosa without the intervention of a submucous tissue consists of bundles of involuntary muscle that are arranged although not with precision as an inner circular layer and an outer longitudinal layer.

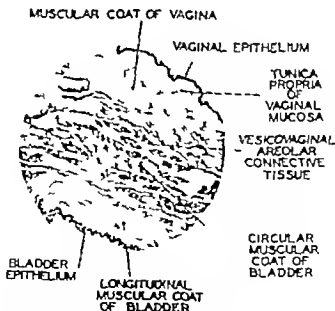

Fig. 7 Low power view of section through the adjacent walls of the bladder and vagina. (From V. Blair Bell.)

The fibrous coat consists of a thin layer of connective tissue which merges into the areolar connective tissue which joins the vagina to the surrounding parts (Piersol). The fibrous coat is in reality a condensation of the vesicovaginal areolar connective tissue.

HISTOLOGY OF THE NORMAL BLADDER WALL

The normal bladder wall (Fig. 4) consists of four coats: the mucous, the submucous, the muscular, and the fibrous.

The mucous coat varies in thickness with both location and the degree of contraction. Over the vesical trigone where always comparatively smooth, it is thin, measuring only about 1 millimeter, where strongly wrinkled by contraction it may attain a thickness of 2 millimeters. The mucosa resembles closely that of the renal duct, consisting of a fibro-elastic tunica propria covered with transitional epithelium.

The submucous coat, loose and elastic, permits free gliding of the mucous over the muscular tunic when readjustment becomes necessary during contraction. It is not sharply defined from the adjoining coats but blends with the stroma of the mucosa on the one side and extends between the tracts of the muscu-

lar coat on the other. Beneath the trigone a distinct submucous layer is wanting or is replaced by a sheet of muscular tissue.

The muscular coat thicker than the mucous varies according to the condition of the bladder being thin during distention and thick in strong contraction when it may measure as much as 1.5 centimeters. The bundles of involuntary muscle are arranged in two fairly distinct layers—a thin outer longitudinal and a thick inner circular layer. Inside the latter and virtually within the submucosa lies an incomplete additional layer. This innermost layer is represented by isolated and indefinite muscular bundles that are blended with the connective tissue. Over the vesical trigone however this layer becomes condensed and forms a compact transverse muscular sheet that is closely united to the overlying mucous membrane and in conjunction with the muscular tissue of the urethra surrounds the beginning of that canal with a constrictor like tract, the internal vesicle sphincter.

The outer fibrous coat is strongest over the inferior surface where it receives reflections from the fascia endopelvina. Over the posteroinferior surface it blends with the vesicovaginal areolar connective tissue (Pierson).

HISTOLOGY OF THE NORMAL URETHRAL WALL

The wall of the normal female urethra (Fig. 5) consists of a mucous membrane supplemented by an outer muscular tunic.

The mucous membrane is composed of a tunica propria rich in elastic fibers and provided with a highly developed system of venous plexus covered with stratified squamous epithelium that above resembles the vesical type and below that of the vestibule. Urethral glands are represented by small groups of tubular alveoli that open by minute orifices on the mucous surface. The mucosa is also beset with small pit like depressions into which the ducts of the glands frequently open.

The muscular coat of the urethra comprises intrinsic unstriated fibers and extrinsic striated

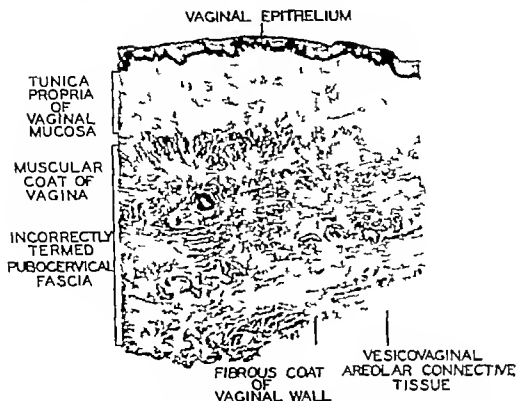

Fig. 11 Section of anterior vaginal wall in a case of large cystocele taken from the lateral part of the wall midway between the urogenital trigone and the cervix.

fibers which are situated outside the unstriped fibers. The unstriped fibers are arranged in an inner longitudinal and an outer circular layer the two being separated by an intervening stratum of areolar tissue (Piersol). The striped fibers are located on the anterior and lateral walls and are absent on the posterior wall—the wall adjoining the anterior vaginal wall. At the extremities of the urethra they form sphincters.

A perusal of the authoritative texts on histology reveals the fact that histologists are unanimously agreed on the histology of the vaginal wall, the bladder wall and the wall of the urethra. In no instance has any histologist described a layer of closely felted fascia in the walls of the vagina, the urinary bladder or urethra. It is apparent therefore that gynecologists who contend that there is a layer of closely felted fascia in the vaginal wall just beneath the mucosa ignore irrefutable histologic facts.

THE NORMAL VESICOVAGINAL SEPTUM

Ricca in an exhaustive review of the literature calls attention to the fact that Jacob

Henle in 1866 first described the normal intact vesicovaginal septum. Henle published a hand drawing of a cross section through the intact septum (Fig. 6), in which he illustrates all of the tissues from the vaginal epithelium to the epithelium of the bladder. This drawing clearly demonstrates that there is no layer of closely felted fascia in the vesicovaginal septum. It does show however that there is between the muscular coat of the vaginal wall and the muscular coat of the bladder wall a delicate layer of areolar connective tissue. Referring to this tissue as illustrated by Henle Ricca has stated "His text contains a hand drawing of the microscopy of the *fascia vesicovaginalis*—a loose areolar mesh." Because of the fragile character of this vesicovaginal areolar connective tissue it is not involved in the etiology of cystocele. In the surgical correction of a cystocele its only role is to guide the operator along a line of natural cleavage between the muscular coat of the vaginal wall and the muscular coat of the bladder wall. It cannot be dissected as an individual layer and it cannot be sutured in operations for cystocele. Henle's description of the vesicovaginal

1. 2. Section through the middle of the vagina in the middle of the length of the vagina. The diagram shows the pelvic region with various anatomical structures labeled. The floor of the space of Retzius is indicated at the top, and the anterior vaginal wall is indicated at the bottom. The diagram also shows the relationship between the bladder, uterus, and rectum, with labels 1 through 7 indicating specific points of interest.

lar coat on the other. Beneath the trigone a distinct submucous layer is wanting or is replaced by a sheet of muscular tissue.

The muscular coat, thicker than the mucous, varies according to the condition of the bladder, being thin during distention and thick in strong contraction, when it may measure as much as 1.5 centimeters. The bundles of involuntary muscle are arranged in two fairly distinct layers—a thin outer longitudinal and a thick inner circular layer. Inside the latter and virtually within the submucosa lies an incomplete additional layer. This innermost layer is represented by isolated and indefinite muscular bundles that are blended with the connective tissue. Over the vesical trigone, however, this layer becomes condensed and forms a compact transverse muscular sheet that is closely united to the overlying mucous membrane and, in conjunction with the muscular tissue of the urethra, surrounds the beginning of that canal with a constrictor-like tract, the internal vesicle sphincter.

The outer fibrous coat is strongest over the inferior surface where it receives reflection from the fascia enloperivina. Over the postero-inferior surface it blends with the vesicovaginal areolar connective tissue (Piersol).

HISTOLOGY OF THE NORMAL URETHRAL WALL

The wall of the normal female urethra (Fig. 5) consists of a mucous membrane supplemented by an outer muscular tunic.

The mucous membrane is composed of a tunica propria, rich in elastic fibers and provided with a highly developed system of venous plexus, covered with stratified squamous epithelium that above resembles the vesical type and below that of the vestibule. Urethral glands are represented by small groups of tubular alveoli that open by minute orifices on the mucous surface. The mucosa is also beset with small pit-like depressions into which the ducts of the glands frequently open.

The muscular coat of the urethra comprises intrinsic unstriated fibers and extrinsic striated

Fig. 14. Operation for cystocele (Type 3). Step 1: The vaginal mucosa is dissected from the underlying muscular coat of the anterior vaginal wall (incorrectly termed pubocervical fascia). The bladder has been separated from its abnormal vaginal and uterine attachments.

tion of the vesicovaginal areolar connective tissue.

To the modified muscular coat of the vaginal wall in cystocele the term musculo-fascia has been incorrectly applied. The inaccuracy of such a term is apparent when one realizes the fact that this coat consists of approximately 80 per cent smooth muscle fibers. The irregularly arranged interfascicular connective tissue found in this layer does not constitute a fascia in any sense of that term. Bissell in 1929 deplored the application of the term fascia to the modified muscular coat of the vaginal wall in cases of cystocele.

The above description of the histologic changes in the vaginal wall in cystocele has been based upon the histologic examination of sections which include all tissue from the vaginal epithelium to the fibrous coat of the bladder. These sections have been made at various levels and locations in the vesicovagi-

Fig. 15. Step 2: The muscular coat of the anterior vaginal wall (incorrectly termed pubocervical fascia) is sutured in the sagittal plane after the removal of the redundant part. nal septum in cases of cystocele of all degrees of size.

CLASSIFICATION OF OPERATIONS FOR CYSTOCELE AND URETHROCELE

The vaginal operative procedures for the correction of cystocele and urethrocele in which the principal feature has been the utilization of the so called pubocervical fascia are of four types (1) A type of operation in which the vaginal mucosa is denuded over a geometric design and the redundant part of the pubocervical fascia is infolded by sutures which also approximate the cut edges of the vaginal mucosa. Sims, Emmett and their contemporaries employed this type of operation. (2) A type of operation (Figs. 12 and 13) in which bilateral flaps of vaginal mucosa are dissected from the redundant pubocervical fascia which is then inverted by sutures. The excessive part of the mucosal flaps is removed and the cut edges are approximated in the sagittal plane of the body. (3) A type of operation (Figs. 14 and 15) in which the vaginal wall is opened in the sagittal plane from a point 1.5 centimeters posterior to the urinary meatus to a point at the level of the cervico-vaginal junction by an incision which passes

Fig. 2. Operation for cystocele (Type 1). Step. The vaginal mucosa is dissected from the underlying muscular coat of the anterior vaginal wall (incorrectly termed pubocervical fascia).

septum was corroborated by W. Blair Bell (Fig 7) in 1910 by Goff (Fig 8) in 1931 and by Koster in 1936.

THE NORMAL URETHROVAGINAL SEPTUM

The structure of the urethrovaginal septum (Fig 9 and Fig 10) differs from that of the vesicovaginal septum in one important respect. Between the muscular coat of the vaginal wall and that of the bladder wall there is a layer of areolar connective tissue which is absent in the urethrovaginal septum. In the urethrovaginal septum the muscular coat of the vaginal wall and the muscular coat of the urethral wall fuse so intimately that there is present no line of natural cleavage between them.

Along the line of this fusion there is a considerable amount of interfascicular connective tissue which tends to make the union an extremely firm one. There is no fascia between the wall of the urethra and the wall of the vagina. This fact alone makes the existence of the pubocervical fascia impossible.

Fig. 13. Step. The redundant muscular coat of the vaginal wall is inverted by interrupted sutures. The excess part of the vaginal mucosa is removed and the cut edges are approximated in the sagittal plane of the body.

THE HISTOLOGY OF THE VAGINAL WALL IN CYSTOCELE

The vaginal wall in which there is a cystocele or urethrocele has a characteristic structure (Fig 11). Contrary to the general opinion the vaginal wall is hypertrophied in all of its layers. This hypertrophy is proportional to the size of the cystocele. In the case of an extremely large cystocele of long standing the vaginal wall may range from 0.5 to 1 centimeter in thickness. As a rule the wall is not as thick in the sagittal plane as it is in the lateral part. In either part however there is a thickening of the epithelial layer, a moderate degree of hypertrophy of the tunica propria, and a remarkable hypertrophy of the muscular coat in which there is both a numerical and an individual hypertrophy of the irregularly arranged muscle fibers. In the muscular coat there is also a considerable amount of interfascicular connective tissue. There is a slight increase in the amount of connective tissue in the fibrous coat which is in reality a condensa-

Fig. 14. Operation for cystocele (Type 3) Step 1 The vaginal mucosa is dissected from the underlying muscular coat of the anterior vaginal wall (incorrectly termed pubocervical fascia). The bladder has been separated from its abnormal vaginal and uterine attachments.

tion of the vesicovaginal areolar connective tissue.

To the modified muscular coat of the vaginal wall in cystocele the term musculo-fascia has been incorrectly applied. The inaccuracy of such a term is apparent when one realizes the fact that this coat consists of approximately 80 per cent smooth muscle fibers. The irregularly arranged interfascicular connective tissue found in this layer does not constitute a fascia in any sense of that term. Bissell in 1929 deplored the application of the term fascia to the modified muscular coat of the vaginal wall in cases of cystocele.

The above description of the histologic changes in the vaginal wall in cystocele has been based upon the histologic examination of sections which include all tissue from the vaginal epithelium to the fibrous coat of the bladder. These sections have been made at various levels and locations in the vesicovagi-

Fig. 15. Step 2 The muscular coat of the anterior vaginal wall (incorrectly termed pubocervical fascia) is sutured in the sagittal plane after the removal of the redundant part. nal septum in cases of cystocele of all degrees of size.

CLASSIFICATION OF OPERATIONS FOR CYSTOCELE AND URETHROCELE

The vaginal operative procedures for the correction of cystocele and urethrocele in which the principal feature has been the utilization of the so called pubocervical fascia are of four types (1) A type of operation in which the vaginal mucosa is denuded over a geometric design and the redundant part of the pubocervical fascia is unfolded by sutures which also approximate the cut edges of the vaginal mucosa. Sims Emmett and their contemporaries employed this type of operation. (2) A type of operation (Figs 12 and 13) in which bilateral flaps of vaginal mucosa are dissected from the redundant pubocervical fascia which is then inverted by sutures. The excessive part of the mucosal flaps is removed and the cut edges are approximated in the sagittal plane of the body. (3) A type of operation (Figs 14 and 15) in which the vaginal wall is opened in the sagittal plane from a point 1.5 centimeters posterior to the urinary meatus to a point at the level of the cervicovaginal junction by an incision which passes

through the mucosa and the pubocervical fascia to the line of natural cleavage between the vaginal wall and the bladder wall. Along this line of cleavage the bladder wall is separated from its abnormal vaginal and uterine attachments. Following the mobilization of the bladder wall the mucosa is separated by sharp dissection from the pubocervical fascia which is then sutured in the sagittal plane as an individual layer. The mucosa after the removal of the redundant part is sutured in the sagittal plane as an individual layer over the reconstructed pubocervical fascia. And (4) a type of operation in which the vaginal wall is opened in the sagittal plane from a point 1.5 centimeters posterior to the urinary meatus to a point at the level of the cervicovaginal junction by an incision which passes through both mucosa and pubocervical fascia to the line of normal cleavage between the vaginal wall and the bladder wall. The bladder wall is then separated from its abnormal vaginal and uterine attachments. Following the mobilization of the bladder wall the redundant part of the vaginal mucosa and the pubocervical fascia is removed as a single layer and the cut edges are united in the midline as one layer.

In the above descriptions of operations the term pubocervical fascia is incorrectly applied to the muscular coat of the vaginal wall.

The anatomic and histologic facts herein enumerated are agreed upon by all authoritative anatomists and histologists. They constitute proof positive that there is no closely felted layer of fascia in or between the walls of the vagina, the urinary bladder or the urethra. They show that there is a delicate layer of areolar connective tissue between the vaginal wall and the bladder wall which because of its fragile structure is not involved in the etiology of cystocele. It is apparent there-

fore that cystocele and urethrocele are not caused by a defect in or an injury to a layer of fascia. It is equally apparent that those who believe that the pubocervical fascia is an anatomic entity must revise their concept of the etiology of cystocele and urethrocele if they are inclined to conform to firmly established histologic facts. The etiology of cystocele and urethrocele is a subject for future discussion.

CONCLUSIONS

- 1 There is no fascia in the walls of the vagina, the urinary bladder or the urethra.
- 2 There is no fascia between the vaginal wall and the urethral wall.
- 3 Between the wall of the vagina and the wall of the bladder there is a delicate layer of areolar connective tissue which because of its frail structure is not involved in the etiology of cystocele. There is no layer of closely felted fascia in the cervicovaginal septum.
- 4 The term pubocervical fascia has been incorrectly applied to the muscular coat of the vaginal wall.
- 5 There is no pubocervical fascia in the human pelvis.

STUDIES ON ECK FISTULAS IN DOGS

A Simple Technique for the Preparation of a Portacaval Anastomosis with the Aid of a Clamp

SMITH FREEMAN Ph D., M D., Chicago Illinois

PORTACAVAL anastomosis has been used as a means of studying the role of the portal circulation in the maintenance of liver function. The procedure is of current interest as a means of reducing portal hypertension in patients with cirrhosis of the liver. By the obstruction of the portal vein above this anastomosis it is possible to deprive the liver of approximately two-thirds of its blood supply. However the response of dogs which have had Eck fistulas made varies considerably; some animals can be maintained in good condition for several years (1) while others rapidly lose weight after the anastomosis is formed (2). It is apparent to one who has made this anastomosis by the cutting suture technique as described by Fishback that the size and patency of the stoma in different animals may vary considerably as a result of the anatomical variations in the relation of the portal vein to the inferior vena cava and of differences in the shape of the chest factors which influence the accessibility of these structures to the surgeon. Postmortem examinations at different intervals after Eck fistula formation reveal that in some animals the anastomosis remains patent while in others it tends to grow shut or to be greatly narrowed. These observations prompted a search for a more uniform and reproducible means of forming a communication between the two vessels in question. Theoretically it seems preferable to have a stoma of fixed and invariable size. To secure such a stoma, however would entail the use of a foreign object such as a vitallium cuff and its use would make the operation technically difficult in the dog. Since few foreign objects are well tolerated by the tissues over an extended period of time, it was decided to seek a method of

producing a more satisfactory stoma between two vessels without connecting them by means of a foreign object.

To assist in this purpose a clamp was necessary which would enable fixation and maintenance of the two vessels in definite relation to one another which would exclude blood from the operative field without completely obstructing either vessel, and which could be applied from the ventral surface of the vessels without extensive dissection or mobilization of them. The blood vessel clamps already described in the literature seemed unsuitable for this purpose. An attempt to use the Potts-Smith (4) clamp for this purpose was unsuccessful.

The clamp which was devised fulfills the three requirements mentioned. However practically complete occlusion of the portal vein may occur if the vessel is unusually small or if the relation between the two vessels is such that the anastomosis must be made distal to its usual location on the portal vein. Once the clamp is securely applied one can incise the vessels and form the anastomosis without hurry or blood loss. By means of this procedure portacaval anastomosis has been made in approximately 30 dogs. Some of these animals were used in the Eck or reverse Eck fistula experiments while in other instances the anastomosis was part of a one stage hepatectomy as described by Markowitz.

PROCEDURE

Usually dogs weighing 30 pounds or more are used for this operation. With the anesthetized animal secured on his back the surgeon makes a midline abdominal or right rectus incision from the ensiform process to the penis of the male dog, or one slightly longer in the female animal. The intestines are retracted to the left side of the abdomen and

Fig. 1 shows the technique of making a portacaval anastomosis with a clamp.

Fig.

are covered with a laparotomy pad. The hepatorenal ligament is cut and a laparotomy pad is placed over the surface of the liver and the left side of the incision.

The peritoneum, fat, lymphatic and fine blood vessels overlying the portal vein are completely cleared by blunt dissection from that portion of the portal vein which lies next to

the vena cava. The vena cava above the renal vein and below the liver is freed of fat and peritoneal attachments on the side next to the portal vein. After both vessel walls have been carefully exposed and cleared of overlying

Fig. 4.

Fig 5

tissue stay sutures¹ are passed through opposite points of both vessels (Fig 1) at sites which will eventually be the two extremes of the anastomosis the suture closest to the liver just distal to the pancreatic vein is secured first. The distal suture is placed approximately one inch² from the first one at a point which is usually just rostral to the first visible branch of the portal vein—the stay sutures are approximately 8 inches long. Next the open clamp is held vertically with the handle side cephalward while the stay sutures are passed through its open jaws (Fig 2). Then as the clamp is applied to the vessels traction is made on the stay sutures. The surgeon manipulates the clamp and upper stay suture from the right side while an assistant retracts the abdominal wall and places traction on the lower stay suture. When the portion of each vessel between the jaws of the clamp is similar and adequate the clamp is closed until the vessels are held firmly. There should be $\frac{3}{8}$ inch to $\frac{1}{4}$ inch width of each vessel protruding between the jaws of the clamp for a distance of 1 inch. Once the vessels are secured the clamp is held in position by the assistant who exerts gentle traction as required for adequate ex-

Fig 6

posure. Sutures for retraction of the lateral wall of each vessel are next secured to the mid portion of each vessel just lateral to its crest (Fig 3). By means of a fine sharp-pointed knife (e.g. cataract knife) or scissors each vessel is incised longitudinally just medial to its crest and near its lateral stay suture. The

Fig 7 Eck fistula completed.

¹Carrel 20 mm. straight arterial needles and No. 5-0 or 6-0 black silk are used for the stay sutures and anastomosis.

²For dogs weighing 35 lbs. or more, a larger sized clamp is used which permits the stay sutures to be placed $\frac{1}{4}$ inches apart.

TECHNIQUE OF LOW THIGH AMPUTATION

WILLIAM D HOLDEN MD FACS Cleveland Ohio

THE care of patients with arteriosclerotic ischemic necrosis of the lower extremity still presents many unsolved problems. The correction of altered glucose fluid electrolyte and protein metabolism has promoted to a considerable degree the successful management of these patients. The intensive administration of antibiotic and chemotherapeutic drugs has for the most part eliminated pyogenic infections as a major cause of death. Revitalization of tissue completely necrotic remains impossible and allows recourse to no form of therapy save spontaneous or surgical amputation.

Although some difference of opinion still exists concerning minor details of thigh amputation, there has evolved during the past two decades a general agreement upon the principles of this operation. The combined contributions of McKinnick, Samuels, Callender, Pearl, and others have simplified the technical aspects of low thigh amputation.

There has been a growing conviction that amputation of the lower extremity through the lower third of the thigh is more satisfactory than amputation at either a higher or lower site. It is true that there are definite indications, such as occlusion of the common femoral artery or rapidly advancing anaerobic infection, for performing amputations at a higher level. In the absence of such indications, however, no purpose is served by a high amputation. The difficulty in obtaining viable dermo-fascial flaps below the patella has for the most part led to abandoning transtibial amputations for arteriosclerosis obliterans.

The practice of subjecting a patient to a lumbar sympathectomy in order that amputation below the patella may be performed has not seemed justified unless there is reason to believe that the amputation can be successfully accomplished through the metatarsal area or distal to this site. There are very few

patients with ischemic necrosis of the toes or foot who are candidates for sympathetic interruption of vasomotor tonus. This does not apply to patients who have pain because of arteriosclerotic ischemia. Patients carefully and conservatively selected in this group may be afforded gratifying relief following lumbar sympathectomy. Atlas de Takats and Freeman have shown this to be true and our own experiences have confirmed their results.

During the past 2 years 35 amputations through the lower thigh have been performed for ischemic necrosis at University Hospitals of Cleveland. The neurovascular residents or the author have performed all the operations. The technique to be described has been used in all the procedures. The development of this technique arose from observing amputations performed by many different surgeons. The customary method of low thigh amputation consists of making anterior and posterior dermo-fascial flaps or a circular incision just above the condyles of the femur. The quadriceps tendon and the medial and lateral musculotendinous bands are cut. The sciatic nerve and popliteal vessels are dissected free and ligated. The femur is transected and closure performed. This technique usually demands alternate internal and external rotation of the thigh. During the course of fashioning the posterior flap and dissecting the popliteal vessels, the extremity is commonly held aloft by an assistant. It is not unusual to observe the surgeon in various awkward positions such as bending far over the operative field or assuming a squatting position while directing his attention to the posterior aspect of the thigh. The ease with which contamination of the sterile field can and does occur during this maneuvering on the part of the surgeon and his assistants is quite apparent.

It should be stated emphatically that operating speed is not to be commended when it is obtained by means of poor hemostasis, rough manipulation of tissues and increased risk

From the Department of Surgery, Western Reserve University School of Medicine and University Hospitals.

Fig. 1

Fig. 2

to the patient. The simplicity of the procedure to be described however allows the extremity to be maintained in one position during the entire operation. It allows no blunt dissection, minimizes blood loss and shock and permits completion of the procedure within 10 to 20 minutes. The neurovascular residents who perform all amputations for vascular disease on staff patients adopt the technique with ease.

OPERATIVE PROCEDURE

Intravenous sodium pentothal, cyclopropane, spinal or refrigeration anesthesia are employed according to indication. Spinal anesthesia is preferred and used in the majority of patients. Refrigeration is used only when the patient is admitted with an acute progressing infection superimposed on arteriosclerotic ischemic necrosis.

The patient is placed flat on his back and the skin of the lower extremity is prepared from upper thigh to midcalf with 70 per cent alcohol and a one to five thousand solution of mercury bichloride. Figure 1 shows the position of the extremity from an anterior and lateral viewpoint. One moist sterile towel is wrapped around the midportion of the thigh and another about the leg just below the knee. Sterile sheets are placed beneath the extremity from the gluteal fold beyond the foot of the operating table. The leg and foot which have been held at an angle of 45 degrees from the table during the preparation are then enclosed in a sterile square table cover and wrapped loosely with sterile gauze. A double sterile sheet is then placed over the upper thighs and lower abdomen so that the lower border approximates the lower border of the sterile towel wrapped about the thigh. The sheet

Fig. 3

Fig. 4.

is clipped to the towel. The entire field is then covered with a lap sheet after the extremity is inserted through the central opening. This is done in order that the extremity may be removed from the operative field as soon as the amputation has been effected. A sterile block of wood (Figures 1 and 2) 8 by 6 by 1 inches is placed beneath the popliteal space. A tourniquet is never used except in the rare instance that refrigeration anesthesia is employed. The extremity is flat on the table and is never moved during the operation.

A horseshoe shaped incision is made on the anterior surface of the thigh (Fig. 1). The base of the incision lies at the upper border of the patella. The incision includes skin, subcutaneous tissue and fascia. The great saphenous vein is identified, clamped and ligated with No. 0 chromic catgut. The quadriceps

tendon is incised and the entire dermofascial flap is elevated in this manner exposing the anterior aspect of the femur (Fig. 2).

A periosteal elevator (Figure 3) is used to remove the periosteum from the anterior and lateral aspects of the femur for a short distance about 5 centimeters above the condyles. A small curved hemostat is inserted behind the femur where the periosteum has been removed. A Gigli saw is drawn through. The saw is represented on Figure 3 by the dotted line at the proximal end of the exposed femur. The femur is then transected by using the saw in a lateral to-and-fro motion. Too much vertical tension will cause the saw to break. The wound is washed with saline during transection of the femur. A hand saw is not used because of the danger of injuring the popliteal vessels.

Fig. 5

Fig. 6

The distal end of the femur is angulated medially (Fig. 4). The popliteal vessels are easily visualized, dissected free, clamped, cut, and ligated doubly with No. 0 chromic catgut. The sciatic nerve is also readily identified. If its accompanying small artery is readily visualized

lized it is ligated separately. Gentle traction on the nerve is made and it is sharply cut with a knife. It then retracts. Neither alcohol nor procaine is injected into the stump of the nerve.

Figure 5 shows a lateral view after the popliteal vessels and the sciatic nerve have been cut. The dotted line in this figure indicates the line of incision for the posterior dermo-fascial flap. An amputation knife is employed for this incision which starts within the wound at end of femur and continues obliquely outward and downward through the musculotendinous bands of the semimembranosus, semitendinosus and biceps femoris. The posterior fascia is incised and the incision terminates through the skin at the lower border of the popliteal fossa. The amputated leg is removed from the operative field.

The square corners of the posterior dermo-fascial flap are then excised (Figure 6). Four or five interrupted sutures of No. 0 chromic catgut are used to approximate the anterior and posterior layers of fascia over the stump of the femur. Interrupted silk sutures approximate the skin in eversion. No drains are used. Dry sterile dressings and a neurological roll are applied. Figure 7 shows a stump on the eighth postoperative day.

DISCUSSION

This operation has been performed 35 times during the past 2 years with one postoperative death from uremia on the tenth day following operation. Necrosis of the skin flaps occurred in 1 patient who developed a retrograde thrombosis of the superficial femoral artery extending into the common femoral artery. All of the patients had arteriosclerotic ischemic necrosis and all had superimposed pyogenic infections. All of the operations were performed by the neurovascular residents or the author. Although it is felt that the technical aspects of the procedure contributed beneficially to the welfare of these patients, considerable attention was devoted to the preoperative cor-

Fig. 7

rection of anemia, dehydration, cardiac decompensation, acidosis and other complications commonly seen. Penicillin was administered routinely. Postoperative activity was encouraged. The wounds were first dressed on the fifth postoperative day.

Although the technical aspects of this method of thigh amputation were not found in the literature, a complete survey was not possible because of the inaccessibility of some foreign journals.

SUMMARY

A technique of low thigh amputation is presented. The principal advantages are the facility with which the operation is performed, the elimination of awkward maneuvering by the surgeon, the reduction of potential sources of contamination, the minimal amount of blood loss and tissue trauma and the ease with which patients stand the procedure.

BLOOD BANK ORGANIZATION

PAUL I. HONWORTH, M.D. Ph.D. F.A.C.S. Cincinnati Ohio

DURING the ten year period before the last war physicians began to use progressively increasing amounts of whole blood and plasma in the treatment of patients. This increase was a direct result of better and more popular acquaintance with the value of blood as a therapeutic agent as proved by exhaustive experimental and clinical investigation. The demand soon was so great within hospitals that it became desirable to store these substances in advance of need in order to avoid dangerous and wasteful delays in emergencies and to insure satisfactory and prompt transfusion therapy. A need for improvement in the many technical aspects pertaining to the drawing, storage, preparation and administration of these substances naturally followed and these were brought to a satisfactory stage of development through the work of a host of independent investigators.

Throughout the period of the war physicians in both military and civilian practice further observed the value of blood and plasma and popularized its use in shock and hemorrhage in sepsis and anemia, and in parenteral alimentation for many other diseases. Meanwhile the production, supply and administration of blood and plasma and its derivatives for patients in the armed services through the co-ordinated efforts of individual investigators, military physicians, universities, the National Research Council, The American National Red Cross, and commercial drug firms, developed with amazing rapidity to the point of satisfactory operation.

In civilian practice comparable strides in the provision of blood and plasma have not been made either during the war years or in the postwar period. Limitations imposed by the war, chiefly the demands on medical personnel and the necessary restrictions on ma-

terial were such that little progress was possible throughout its duration. It is now 3 years after the end of the war and the restrictions no longer exist yet the problem of blood bank organization adequate to meet the needs of every community is unsolved. In order to contribute to its solution let us first state clearly the needs, and then examine critically possible methods for their satisfaction. Every hospital in America should have immediately available properly prepared whole blood and plasma in suitable form and in amounts sufficient to meet the needs of practice within that hospital. This is the ideal but for purposes of practicability minor compromises can and should be made under any organizational plan. Adequate medical care however cannot be compromised and it must include blood and plasma service that meets the requirements of the patient, the physician and the hospital.

The first and most obvious solution to the problem is that of the individual hospital supplying its own blood and plasma. This is done in many hospitals but there are natural obstacles which stand in the way of a completely adequate service. The chief of these is the difficulty of maintaining without waste a sufficient inventory of blood of the various groups and of plasma reserves to satisfy all requests. This is even more true since attention must now be paid to the Rh factor. For example only about 1 donor in 350 has blood of group AB Rh negative, 1 in 60 of group B Rh negative and 1 in 16 of group A Rh negative or O Rh negative. Substitutions may be made in some instances but they are also limited. Other obstacles to a complete service within a single hospital include the depletion of whole blood inventory to provide plasma reserves, the cost of equipment, trained personnel and proper supervision and space requirements.

In discussing conditions within the individual hospital it is not meant to imply that hospitals in general cannot manage most of their own blood transfusion obligations sim-

From the Department of Surgery, College of Medicine of the University of Cincinnati, and the Cincinnati General Hospital. Presented before the Clinical Congress of the American College of Surgeons, New York, September 2, 1947.

ply, effectively and economically. Those hospitals large enough to maintain a pathologist, a clinical pathologic laboratory, and a resident house staff are equipped with the necessary personnel. In almost all hospitals the clinical pathologist is a physician of high intellect well versed in the theoretical and practical phases of safe blood transfusion. Improved apparatus which facilitate the transfusion of blood properly preserved in closed pyrogen free containers are available at low cost from commercial houses, as are grouping and anti Rh testing serums of excellent titer and specificity. In most instances in which blood transfusion is desired the proper donor may be found among friends of the patient without undue delay and reserves of blood are not needed. In the larger hospitals (those of 300 or more beds) small blood bank organizations can properly be operated further to fulfill blood transfusion obligations. These functions are ably performed by the hospitals and their staffs and they should continue to maintain self reliance by participating to the limit of their respective abilities.

Since the ability to meet the circumstances naturally varies greatly with individual hospitals, it follows logically that blood bank organization within a community should be devised to supplement the hospital service in accord with the particular needs. For example, one hospital may care to use the central organization only when friends of the patients cannot be located or when available donors or reserves of blood are not of the compatible blood group or when an emergency exists which does not permit waiting for laboratory search. A smaller hospital lacking personnel may find it more suitable to rely upon the organization as a source for all blood used. In the relatively few instances in which plasma is more desirable than whole blood, all hospitals except those large ones properly equipped to prepare their own plasma would rely upon the central organization.

The problem as it exists within the individual hospitals has been reviewed in order to fix the amount of help required to make complete a blood transfusion service for any given community. This step is necessary if the problem is to be approached intelligently and conflict

with existing functions within the hospital avoided. Nine years ago in the greater Cincinnati area a community blood and plasma transfusion center was organized according to this concept. It has met with considerable success. At this point it seems desirable to trace its growth, describe how it operates, and refer to some of its accomplishments.

The project was designed in the Department of Surgery at the University of Cincinnati and the Cincinnati General Hospital and has been in operation since December 10, 1938. Its pioneer development was sponsored by the Cincinnati and Hamilton County Chapter of the American Red Cross, though it was without precedent for a local chapter of the American Red Cross to collaborate with a university in order to produce such an organization. In the first few years of operation the blood bank was used largely for the benefit of patients in the Cincinnati General Hospital, all of whom are on a free medical service basis. A nominal charge was made to the occasional private hospital patient requiring bank blood. As this phase of the service expanded, the Red Cross felt that it was being put in the position of selling blood, which was in conflict with its policy. At the same time the service had become self supporting and transfer of sponsorship could be made without requiring a subsidy. On January 1, 1944, at the request of the Red Cross, sponsorship was transferred to the University of Cincinnati and the project is now known as the University Blood Transfusion Service. It operates for the Cincinnati General Hospital and for 15 hospitals in the metropolitan area.

The office and laboratory facilities and details of the methods, technique, and equipment used in the drawing of blood and in the preparation and processing of plasma have been described elsewhere (1, 2, 3, 4, 5, 6). The service is directed by a member of the attending staff of the Department of Surgery. A secretary, 6 laboratory technicians, a graduate nurse, and a diener are employed and a number of part time volunteers, some of whom are Red Cross nurses aides, serve at regularly scheduled hours.

The service provides whole blood, plasma in the liquid, frozen, and dry states, and red

blood cells in dextrose solution. Plasma production has been suspended since the Army and Navy surplus was made available but will be resumed when this supply is exhausted. Ordinarily all hospitals participating in the service are given a supply of plasma for use in emergencies. Whole blood is dispensed only at the request of a physician for a specified patient. Whenever a unit of whole blood or plasma is issued the information needed by the service is entered on a printed form which records the amount of whole blood or plasma desired, the name of the patient, the method of repayment if it has been decided upon, the signature of the physician and the signature and address of the responsible relative or friend. Neither the physician nor the hospital assumes any responsibility for seeing that repayment is made. The physician is asked merely to explain the obligation to the patient or his relative at the time the slip is signed and the hospital simply to see that the service receives the forms properly filled out.

Much of the success of this project is due to the fact that repayment of the obligation to the service is made according to the circumstances of the patient and his family. These circumstances are indicated on the request forms by the physician. Most patients fall in to one of four classifications. If the patient is financially able and has willing blood donors the charge is \$12.50 and one donor for each unit of blood (500 c.c.) or plasma (250 c.c.) if he is financially able and has no willing donors the charge is \$25.00. If he has willing donors but is poor, two suitable donors are accepted for each unit used. If the patient is indigent and has no friends willing and able to serve as donors, the blood or plasma is supplied without obligation out of reserves obtained from those repaying with two donors. Red blood cell suspensions are a by-product of plasma preparation and are charged for at one-half these rates. All classifications are flexible and obligations are always adjusted to meet the circumstances. For example, if the patient who is neither indigent nor well-to-do has received many units of blood or plasma and has been subjected to the expense of protracted hospital and medical care, any part of the accrued obligation either in blood donors or in

money is acceptable as payment in full. A statement by the patient's doctor as to the limit of the ability to pay is accepted as final. In any event no method of collection other than a simple statement of obligation is ever used. At no time during the 9 years of operation of this service has a request for blood or plasma been refused, the reserves have never been exhausted and no blood has been purchased from donors by the service.

Donors present themselves at central headquarters during 3 regularly scheduled half-day periods each week. At these times a physician is present to draw the blood. He is paid by the participating hospitals, the share of each being prorated according to the number of transactions during the preceding month. In 1946 this amounted to about 20 cents for each transaction. There is no other charge made to hospitals by the service.

In a few respects the operation of the service for patients in the Cincinnati General Hospital differs from that for patients in other hospitals. Since patients in the General Hospital are on a free medical service basis, all repayment is made with blood donors on a unit for unit basis and no cash payments are ever received from patients. In return the General Hospital provides the service with space, heat, light, laundry and some chemicals.

The usefulness of this service to the community is indicated by its growth expressed in terms of the number of transactions in units of whole blood and plasma. During the years of operation there has been a progressive increase from 2,687 units for the year 1939 to 8,025 units for the year 1945. This dropped to 7,152 units in the year 1946 because of the use of free government plasma to supply part of the demand. From 1943 to 1946 inclusive, 15,248 units of whole blood and plasma were issued to the General Hospital and 13,136 units were issued to other participating hospitals making a total of 28,384 units of whole blood and plasma for the 4-year period.

The financial operation of the service has been satisfactory. Expenditures consist of salaries for secretarial and technical personnel, supplies for the office and laboratory including grouping serum and all items used in donor sets, and maintenance in the general

headquarters and on refrigeration and laboratory equipment. There is no salaried medical direction. The income to the service is derived entirely from patients who are paying for private hospital and medical care and who have received blood or plasma from the service. The total expenditure for the 4 year period from 1943 to 1946 inclusive was \$54 107 18. The total income during this same period was \$87 060 59 leaving a surplus of \$32 953 41 despite the fact that more than half the transactions involved patients making repayment with donors only. This surplus is to be used in the purchase of new equipment for the blood transfusion service when the building program permits new headquarters. Since in the 4 year period from 1943 to 1946 inclusive there were 28 284 transactions in whole blood and plasma and \$87 060 59 in income each transaction cost the service about \$3 00. This cost was paid by the patients who received the benefits at the rate of not more than \$25 00 or \$12 50 and one donor for each unit. In no instance has attempt at collection been more than a simple statement of obligation to the patient and blood and plasma in any amount requested have always been issued regardless of the financial circumstances of the patient.

A description of this service has been made in order to illustrate how the blood transfusion problem has been managed in a single community. It has been moderately successful in its accomplishments but they fall short of being ideal. A careful check reveals that only about 95 per cent of the requests are satisfied promptly. In the remaining 5 per cent there is delay in supplying Rh negative blood of a specified group or blood of group AB and B. A second defect in the service is that no provision is made to serve hospitals in outlying smaller cities and towns. It would not be difficult to extend the service to include these localities by altering the organizational plan. Such an extension would at the same time mitigate the problem of shortages of the rarer groups of blood because of increased inventories that would result.

The service which has just been described obviously will not suit exactly all communities but if it were applied to others throughout the country the plan could and should be

made as flexible as necessary to meet the requirements of each. The variables to be met would be the number and sizes of the participating hospitals and the distances between them. For example by the adoption of standard apparatus and techniques for the drawing of blood hospitals at greater distances might make periodic collections of blood from friends and relatives of patients and transport them to the center in return for a supply of plasma and blood of more useful distribution in relation to the blood groups. Hospitals close to the center might prefer to have the blood collected there and to draw out both whole blood and plasma according to need. The size of the hospital and the degree to which it has developed its own transfusion service would also determine the extent of its reliance upon the center. Schemes of operation would have to vary in order to suit both community and hospital requirements but they would resemble one another in their fundamental objectives. This phase of the problem that of working out details of the plan in a particular community should not prove to be difficult.

In order to develop and put into effect similar blood bank organizations operating from within strategically located cities and have them serve the entire country the impetus must come from an organization capable of dealing with the problems on a nationwide scale. Authority should then be delegated to agents within state or other regional units to co-ordinate the activities in each. The interests of the community would best be served if these agents were physicians associated with medical centers who would then be in a position to understand the problems within the hospitals as well as within the community. These men should be carefully selected for their interest in and knowledge of the theoretical and practical aspects of blood transfusion and for their administrative ability.

SUMMARY

The plan of blood bank organization now in operation in the Cincinnati area has worked effectively and economically for almost 9 years. It could be adopted on a nationwide basis adjusted to suit every community and yet retain its fundamental principles not the

least of which is the preservation of individual responsibility. The patient would receive blood and plasma in the amount needed regardless of his financial circumstances. If payment in money could not be made he still would be allowed to participate by supplying blood donors from his friends and relatives. If he had no willing donors he would not be denied the service. There would be no restrictions placed on the physician either by the amounts of blood or plasma readily available or by the financial ability of his patient.

In the majority of blood transfusion procedures there is enough time and sufficient personnel and facilities within the hospital to secure suitable donors among friends of the patient and to draw and administer the blood. Under a community plan as described the hospital would continue to be self-reliant to the limits of its ability but deficiencies in its service would be complemented.

The service would be paid for by those who receive the benefits without excessive cost to the individual and without the need for a protracted annual subsidy from any source. Because the service would be self-supporting it could not become a financial burden to the community.

A plan to provide blood without charge to all and to finance the project by the use of a subsidy however derived, would be ill advised. This is the most extravagant method of establishing an essential service. There is no such thing as blood without costs. Any transfusion service, whether locally or nationally organized, requires the employment of skilled personnel trained for highly technical jobs. Their services will cost money. These costs, if

not paid by the person who receives blood, must be paid by others. Thus to speak of transfusion service without charge is merely to indulge in double-talk. Such a scheme would discourage the fulfillment of personal obligations and invite charity where it is not needed. It would also by creating among the masses an appetite for gifts and the habit of receiving them build up a mountainous service much of which is not needed because it is already being supplied effectively within individual hospitals. Any organizational plan devised to supplant existing hospital services would become vastly more expensive than one which afforded only the help necessary to make them complete.

Adequate blood transfusion service for every patient is important enough to justify the use of a subsidy if it cannot be avoided. One way of solving the transfusion problem in communities might be the sponsorship of a national program by a scientific organization willing to make an initial subsidy and then turn over control as the local organizations become self-supporting. It is essential to consider methods which preserve the fundamental principles of self-reliance and individual responsibility.

VAGOTOMY AND THE MANN- WILLIAMSON ULCER

THE discovery by Mann and Williamson¹ of a method which regularly leads to the production of progressive peptic ulcers in experimental animals has proved to be of great importance in the study of the pathogenesis of these lesions. It has also made possible an evaluation of various therapeutic procedures both as prophylactic and as curative measures under the controlled conditions of the laboratory. It seems probable that the explanation proposed for the cause of these ulcers is correct namely that they are due to the corrosive effect of the acid gastric content on the jejunal mucosa when deprived of the continuous neutralizing effect of the alkaline duodenal secretions. In this connection however, certain observations made by the present writer are of interest and not easily explained.

Thus when the pancreatic juice in dogs is diverted to the exterior by a fistula of the

type which has been described by Dragstedt, Montgomery and Ellis², progressive ulcers appear in the duodenum in almost every case and are exceedingly difficult to prevent. Total pancreatectomy however which also excludes pancreatic juice from the duodenum, is almost never followed by ulceration. In over 500 of these operations in our laboratory, the incidence of ulcer is less than five per cent. We have not been able to demonstrate that pancreatectomy decreases gastric secretion, so the failure of these animals to develop ulcers remains unexplained.

Although the effect of complete vagotomy on the development of experimental Mann-Williamson ulcers was not investigated before this operation was introduced³ for the treatment of intractable peptic ulcer in man, it has subsequently been studied in our laboratory and simultaneously by several other investigators.^{4, 5, 6, 7} It seems clear that vagotomy has little or no beneficial effect on the occurrence or course of these ulcers. This is in striking contrast to the effect of complete vagotomy in gastrojejunal ulcer in man. Here the ulcers heal⁸ and have remained healed for periods of three to five years. The opinion of almost all surgeons is apparently unanimous that vagotomy is a satisfactory treatment for gastrojejunal ulcer following the performance of either gastroenterostomy or gastric resection in man.

⁸Mann, J. C., and Williamson, C. S. *Ann. Surg.*, 1937, 77: 409.

What is the explanation for this marked difference in response to vagotomy displayed by the experimental as compared with the clinical ulcer? Is the Mann-Williamson ulcer in dogs strictly comparable to the stoma ulcer seen in man? These are important practical as well as theoretical questions.

One obvious difference between the two lesions depends upon the fact that in the experimental ulcer the duodenal secretions are deviated completely into the lower intestine while in most stoma ulcers in man these secretions pass over the ulcer area. An exception to this latter statement is the stoma ulcer that develops when a Roux or Y type of gastroenterostomy is performed. Exalto³ many years ago called attention to the high incidence of stoma ulcers with this type of anastomosis, both when done for duodenal ulcer in man or when constructed in normal dogs. It is quite likely that the pathogenesis of these experimental ulcers of Exalto is similar to that of the Mann-Williamson lesion. The Y type of gastroenterostomy has now been abandoned for the treatment of duodenal ulcer but occasionally stoma ulcers are encountered in man when the situation resembles that in the experimental ulcers of Exalto and of Mann and Williamson.

Two cases of this type have been recently encountered in our clinic and are of interest in that a complete vagotomy failed to prevent their occurrence or permit them to heal. In both cases, vagotomy plus gastroenterostomy was performed for intractable duodenal ulcer with pyloric stenosis. Because of subsequent obstruction to the proximal loop at the site of anastomosis, an entero-entero anastomosis was made between the proximal and distal loops of jejunum. This had the effect of diverting the duodenal juices from the region of the anastomosis and creat-

ing a situation resembling that in the Mann-Williamson ulcer. Progressive stoma ulcers appeared in the jejunum adjacent to the anastomosis in spite of the fact that physiological studies indicated that the vagotomy had been complete. Since these are the only stoma ulcers encountered in a series of 168 complete vagotomies with gastroenterostomy the adverse effect of sidetracking the duodenal secretions from the region of the anastomosis becomes more impressive. It is likewise important to emphasize that we now have evidence both from the laboratory and the clinic that vagotomy will not prevent or cure stoma ulcers that arise under the conditions which have been mentioned.

Considerations such as these make one question the advisability of using the Mann-Williamson preparation as a test object for the efficacy of therapeutic measures proposed for peptic ulcers in man. It is probable on the basis of recent findings that most duodenal and stoma ulcers are due to gastric hypersecretion and that complete absence of the automatic neutralizing effect of the duodenal secretions plays the predominant role in only a few special situations such as those here discussed. Gastroenterostomy is not followed by stoma ulcer unless gastric hypersecretion exists or is experimentally produced or unless the duodenal secretions are diverted from the area of anastomosis. It is for this reason that jejunal ulcers do not occur after gastroenterostomy in normal dogs or in man with carcinoma of the stomach or gastric ulcer associated with normal or depressed secretion. When the excessive gastric secretion characteristic of patients who have duodenal ulcer is returned to normal values by complete vagotomy stoma ulcers do not take place unless the duodenal secretions are diverted from the region of the anastomosis.

³Exalto, J. *Mitt. Grenzgeb. Med. Chir.* 67, 23, 3.

THE PRESENT STATUS OF PULMONARY RESECTION IN THE TREATMENT OF PULMONARY TUBERCULOSIS

SINCE Brauer and Frederick reported the performance of a successful thoracoplasty more than forty years ago, thoracic surgeons throughout the world have been increasingly interested in the surgical treatment of pulmonary tuberculosis. Many new collapse procedures, some good and some bad have been devised and all the acceptable ones have been tested for their therapeutic value. The indications for each have been crystallized and clarified so that we know with reasonable assurance what to expect. While several procedures have been effective there still remains a limited group of patients who are in need of more adequate measures to eliminate tubercle bacilli from the sputum. Under such circumstances it is not strange that pulmonary resection should finally come under careful consideration. During the past ten years resection has been given a trial in an increasing number of patients. The results have been rather unsatisfactory. The technique used in earlier resections necessitated cutting through tuberculous tissue in dividing the hilar structures a step which resulted in many serious complications and often in death. Later with refinements in technique, which included the individual ligation of the hilar vessels, and with a more careful and painstaking handling of the bronchus, results have been improved.

In 1942 46 cases of lobectomy were reported with a mortality of 25 per cent, and 29 cases of pneumonectomy with a mortality of 45 per cent. The satisfactory results were tabulated as 68 per cent for lobectomy and 41 per cent for pneumonectomy. These cases were particularly interesting because in many of them a

diagnosis of tumor or of some other nontuberculous lesion had been made however, following operation the condition was found to be tuberculosis. The indications for operation were varied, among them were tuberculoma, tuberculous bronchiectasis, bronchial stenosis and postthoracoplasty cavity. Complications were common and included fistula, contralateral spread, empyema etc. The best results were reported in that group of patients whose sputum was found to be negative for tubercle bacilli previous to resection.

One might expect the poor results obtained in the early group of cases to act as a deterrent to any enthusiasm which might arise in favor of the procedure. This is not true however, for since 1944 an increasing number of patients have had pulmonary resection performed to relieve a variety of conditions. A sufficient length of time has not yet elapsed to determine what the final results will be. Up to the present the indications for resection have been flexible and have varied widely throughout the country. Certain facts must be kept in mind if pulmonary resection is to rest in the niche occupied by approved methods of treatment. Tuberculosis is not localized in one structure of the body distant foci may lie dormant for long periods, a fact which may permit a false sense of security both to the physician and his patient. Later, through deleterious influences and alterations in physiology, these foci may become active and the disease become more formidable than before. Such relapses are typical of tuberculosis and may have no connection with any form of previous therapy. It is important that each patient who is considered for surgical treatment should be carefully studied and that all the possibilities be weighed by a team consisting of at least an internist and a surgeon with sufficient experience and knowledge of the vagaries of the disease to permit a logical choice of procedure.

Pulmonary resection whether lobectomy or pneumonectomy is a major operation regardless of the pathology present. The loss of respiratory function must be seriously considered both as to its immediate and late effects. The useless sacrifice of normal functioning pulmonary tissue may be ill advised. This statement is borne out by the latest reported results in approximately 400 cases of resection in less than 50 per cent the sputum was negative on culture, in over 30 per cent it was positive and 25 per cent of the patients are dead.

While the indications for resection still vary probably the most outstanding and universally acceptable are (1) Failure of the thoracoplasty. Failure necessarily implies an adequate thoracoplasty which has failed to close a cavity with a resulting bronchiectasis and with the sputum positive for tubercle bacilli. Resection is indicated in such cases when the opposite lung or remaining lobes are free from disease or show only quiescent minimal lesions. (2) Bronchial stenosis which represents a burned out lesion with cicatricial contracture of such a high degree that it interferes with drainage and leads to frequent bouts of recurrent pneumonia, atelectasis, lung abscess, and toxemia. The stenosis may be in a stem or lobar bronchus. (3) Tuberculoma, not infrequently located near the hilum and causing bronchial obstruction cannot always be differentiated from carcinoma. Delay in such cases may in certain instances, invite disaster. (4) Failure of a pneumothorax. Adequate collapse is obtained which is equal to or superior to what might be expected from thoracoplasty but the underlying cavities remain open and the sputum positive. Other indications less clear include (5) Giant cavities. Some prefer in such cases a trial of collapse therapy before extirpation while others carry out resection on the premise that collapse measures will be unsatisfactory. Collapse therapy is to

be preferred if a reasonable chance of success seems likely. (6) Basal lesions which should be treated by means of some type of collapse therapy in the form of artificial pneumothorax, phrenicotomy or pneumoperitoneum, and should be given preference of trial. (7) Hilum lower lobe apical and middle lobe cavities are not readily amenable to thoracoplasty but other minor collapse procedures merit careful consideration.

The most common and serious complications and sequelae after resection are (1) Reactivation or spread of the tuberculous process in the remaining pulmonary tissue, ipsilateral or contralateral. The complete elimination of spread or reactivation is impossible but a more careful and thorough study of the tuberculous process will certainly reduce the frequency of its occurrence. Following lobectomy the forced overexpansion of the remaining lobe or lobes which undoubtedly contain unrecognized healed and unhealed lesions, is dangerous. Thoracoplasty performed either at the time of or at an early date following resection will accomplish three important things. It will obliterate the pleural space left after the resection. It will prevent the overdistention of the remaining lobe, and it will at the same time permit normal function of the lobe. (2) Mixed infection or tuberculous empyema. Early obliteration of the dead space by thoracoplasty and phrenicotomy following pneumonectomy reduces the duration of disturbed respiratory function, lessens mediastinal shift with overexpansion of the remaining lung and reduces the chances of infection, early and late. We have no assurance that a longstanding dead space following pneumonectomy for tuberculous will react any differently than that in those cases of extrapleural pneumothorax or oleothorax in which a tuberculous extrapleural empyema has occurred in 50 per cent of the cases as long as five years

later (3) Bronchial fistula. When a bronchial fistula connects with a large dead space, early infection follows. Such fistulas are most common in cases in which acute tuberculous bronchitis exists at the time of surgery. Until the disease in the bronchus is brought under control, operation should be delayed and other procedures should be used to treat the acute process. This precaution will also reduce the ulceration which is encountered in the bronchial stump and which has been found to contribute to the persistence of tubercle bacilli in the sputum.

Streptomycin has proved to be valuable in the treatment of tuberculosis and should be tried before surgery is instituted particularly if a tuberculous bronchiectasis existed before or continues after thoracoplasty. The drug has given excellent results in acute tubercu-

lous bronchitis. It has also been valuable in controlling and perhaps preventing, acute tuberculous empyema following resection. Streptomycin can be introduced directly into the pleural cavity previous to obliteration by thoracoplasty. Streptomycin gives promise of controlling for a time at least, early post operative spreads.

Resection in pulmonary tuberculosis is not the final answer. It is a dangerous operation and decision to use it must be made only after other recognized collapse procedures have been carefully considered and found wanting. To ignore this warning will bring disrepute to a therapeutic measure which has its place in the treatment of pulmonary tuberculosis. The value of resection can be determined only by the results obtained over a long period of time.

JOSEPH W. GALE.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE second edition and revision of *Normal Encephalogram* by Davidoff and Dyke was undertaken alone by Dr L. M. Davidoff due to the tragic and untimely death of Cornelius C. Dyke on April 23 1913. This very worthwhile book first appeared in 1937 and was written in response to numerous requests from neurological surgeons, neurologists, roentgenologists, pediatricians, and internists. In the fields of all these specialists, encephalography is utilized and basic knowledge of the appearance of the normal encephalogram is essential in order to make correct interpretations of the roentgenograms after the injection of gas.

The object of the book is to present a fundamental thesis on encephalography based not only on the author's experience with many thousands of encephalograms but also a review of the literature on this subject. As stated in the preface to the first edition "The body of the book is concerned with what might be termed encephalographic anatomy. By this we mean the anatomy of the living brain and its coverings viewed by means of the contrasting shadows of tissues and gas in the stereoscopic roentgenogram."

The various chapter headings and contents in the second edition are essentially unchanged from the first edition. There are however, numerous additions and there is a very worthwhile review of all new contributions on encephalography appearing in the recent literature.

Anyone interested in any phase of encephalography will find this volume most valuable.

HOWARD N. LARSEN.

WHEN one contemplates the treatment of a patient who has a surgical disease it is amazing to find how much more is necessary to treat the patient properly than simply knowing the anatomic diagnosis and having the ability to perform a stand and operative procedure. Allusion may be made to just a few items such as hydration, the nutritional status including vitamin balance, blood picture, electrolytes, blood chloride and protein levels, and nitrogen retention. Moreover complicating anatomic disorders must be detected, controlled, or corrected if possible before surgery is attempted. Among these may be mentioned oral sepsis, diabetes, chronic nephritis, coronary disease, prostatic hypertrophy and abnormal mental states.

It is desirable to alter at least to a degree, the methods of teaching of surgery. Too often pro-

cedures and precepts are presented and advocated without giving the reason or philosophy for such. The proper management of a disease in its various stages and in different types of individuals that may have anatomic complications or abnormal physiologic states can be carried out only by one possessing much basic information and the ability to utilize such information to build a correct therapeutic structure. Trusting to memory alone is not sufficient because any surgeon will soon encounter a condition that he has not been specifically instructed about; moreover without reasoning experience less likely will develop his mental stature. Therefore correct teaching necessitates supplying a foundation on which by guidance in thinking and reasoning an accurate mental structure can be erected.

With these points in mind the recent work by Bancroft and Wade has been surveyed rather critically and it is gratifying to state that in general these requirements have been fulfilled. This work *Surgical Treatment of the Abdomen* first appeared in 1941 under the title of *Operative Surgery* and was to be one of several volumes to be published by another publishing house. The plan did not materialize and in time the present publishers arranged for the complete set. Four volumes covering various phases of surgery have appeared: two on surgical treatment of the motor skeletal system, one on surgical treatment of the nervous system and one on surgical treatment of the soft tissues. The present volume which is a complete revision of the original edition is the fifth of the series.

The title of *Surgical Treatment of the Abdomen* belies the scope of this work since there is a section of 145 pages on anesthesia, one of 142 pages on the principles of surgical technique and one of 101 pages on surgery of the mouth including the salivary glands and the esophagus. This is not offered as a criticism of the work but of the title. In fact, the chapters on anesthesia are so comprehensive and lucid that any surgeon would do well to read them. At the operating table just one person is responsible and that is the surgeon. He should know the principles of anesthesia and the facts about any or all that are afforded him. An interesting detail described is the relationship between preoperative sedation and anesthetic used. The pharmacological actions of each agent are described again giving the why for the decisions.

SURGICAL TREATMENT OF THE ABDOMEN. By Frederic B. Bancroft, A.B., M.D., F.A.C.S., and Preston A. Wade, A.B., M.D., F.A.C.S. Philadelphia, London, Montreal: J. B. Lippincott Co. 642.

THE NORMAL ENCEPHALOGRAM. By Leo M. Davidoff, M.D. and Cornelius C. Dyke, M.D. 2d rev. ed. Philadelphia: Lea & Febiger, 1946.

A similar attitude can be taken on preoperative and postoperative treatment. This is well illustrated in a discussion of diabetes in the surgical patient. The problem is carefully analyzed a solution arrived at by common sense reasoning and presented in a concise manner requiring only a few minutes to read. The chapter on the fundamental principles of surgical technique written by the late Mont Reid and Stevenson deserves special attention. Here is described the correct ritual of the operating room. The attention to almost countless details many minor in appearance, which is so essential to a safe prompt and successful conclusion is described in full. One cannot but agree with the senior author when he states in the preface. It really should be read by every surgeon by every resident and by every intern. To this may be added— and adhered to.

Section four is devoted to surgery of the abdomen. The material is presented in a lucid and pleasing manner. Special attention may be drawn to the chapter on peritonitis and peritoneal abscesses by Collier and Ransom. The authors stress the reasons for their conclusions and advice. Chapter 15 on the surgical therapy of lesions of the stomach and duodenum was written by the late Roscoe R. Graham. Much informative material is presented which should guide the surgeon in the line of proper approach to the specific lesion to be treated. His discussion of the ulcer-cancer problem as related to the stomach is concise and definite and should be accepted. Stone in his chapter on the anus clearly demonstrates how a subject that is so frequently neglected and uninteresting to so many surgeons can be made not only interesting and informative but a pleasure to read. Ravdin in his chapter on diseases of the liver gives a concise description of this complicated problem as it is encountered today. His conclusions are founded upon sound scientific reasoning based upon research in this field and close observation on the human subject. The addendum to this chapter on portacaval anastomosis for the relief of portal hypertension by Blakemore is timely and most interesting.

Aside from the portions specifically mentioned this work of 7,026 pages contains chapters on abdominal incisions by Gurd, the significance of gastroscopy for the surgeon by Schindler, gastrojejunal ulcer by Pfeiffer, surgery of the small intestine by Allen and Welch, appendicitis, its surgical treatment by Ochsner, the colon and rectum by Rankin and Graham, surgery of the biliary tract by Whipple, diseases of the pancreas by Parsons, surgery of the spleen by Rives and Mace, and physiologic aspects of post-operative care by Bassler. The material is well arranged. It is enriched by 457 illustrations and 3 colored plates all of excellent quality. Such a large field is difficult to cover completely so that material is in a sequential order and unnecessary repetition is eliminated. The editor has accomplished this in a very commendable manner. The impression gleaned from the work is that in many ways it is a leader in a type of presentation that stresses not only what to do but why.

The chapters by Reid, Graham and Gurd cannot be read without becoming acutely aware of the stupendous loss the profession has sustained in the passing of these great surgeons, scholars, scientists and courteous gentlemen.
JOHN A. WOLFE.

THE textbook *Lehrbuch der Gynaekologie*¹ is the first volume of a three volume series of texts covering the field of gynecology and obstetrics. It has been developed since the war in order to fill the gap which was a result of the apparent loss of much of the textbook material, especially for the practitioner and student. Professor Guggisberg, director of The University Women's Clinic at Bern, has compiled the text and is the author of seven chapters. Professors Hirtzsche, F. Ludwig, C. Müller and Neuweiler contribute the remaining twenty-one chapters.

In this large volume a tremendous amount of material is presented in an orderly, but rather uninteresting fashion. One is immediately aware of the complete absence of any bibliography and the scarcity of any reference to individual work. From the student's standpoint, this would be a rather prominent deficiency in that more extensive study of a specific subject would be impossible with this text as a basis. An extenuating circumstance in regard to this deficit may be the lack of reference material in Germany at the present time. Another rather noticeable omission is that of the detail of operative technique and operative therapy. In general this lack is of little moment to the student or practitioner. However, the more common procedures of hysterectomy and repair should be included.

The caliber of the illustrations in this volume varies considerably. The color photographs are little short of remarkable in detail and subject material. The most striking examples of this art are to be found in the chapters on diseases of the vulva and vagina, carcinoma of the cervix and myoma. These would be outstanding in any book. On the other hand many of the black and white and line drawings are indistinct and too diagrammatic to be of much value. The photomicrographs are in general rather poor although those which were taken of the early malignant changes in the cervix are well done.

The arrangement of chapters in the first half of the volume follows the usual lines. Anatomy, embryology and congenital malformations are covered adequately. The drawings are poor but hysterograms are good. Constitutional and growth disturbances, physiology and functional disturbances are discussed most completely by Guggisberg. The chapter covering the abnormalities of menstrual flow, disturbances of secretion and pain is extremely well done. Here again however is a photomicrograph of "glandular cystic hyperplasia of the endometrium" which to all the world looks like an advanced secretory endometrium. The pathogenesis of the organic and

¹LEHRBUCH DER GYNAEKOLOGIE. By Prof. Dr. Hans Guggisberg. Band 1. Karger, 1946.

functional disturbances and diagnostic procedures conclude the chapters on general topics.

Muller's material on diseases of the vulva and vagina and Neuweller's on diseases of the uterus are certainly to me the best in the text and of this group the discussion of myomas with therapy is outstanding. Here also are to be found the beautiful color photographs which add much to the value of the work. Interesting to note here is the use of intra-cervical and intrauterine sclerosing solutions as part of the treatment of abnormal uterine bleeding. Also the mortality figures on the Wertheim procedure are those of past years. Meigs, his coworkers, and others have improved materially on the 15 per cent quoted by Neuweller.

Diseases and tumors of the ovary are covered briefly. Incidence of malignancy is missing in cases of special tumors. The classification is as good as the majority of classifications of ovarian tumors. Diagnostic points are well taken. Discussion of diseases of the tubes is quite brief. Tubal pregnancy is not included here and is only mentioned in several other chapters. Possibly it is covered in another volume.

Infections of the genitalia, malpositions of the uterus and endometriosis are separated from other discussions of diseases of the genitalia by chapters on extragenital lesions associated with gynecological disease. Diseases of the pelvic connective tissue, abdominal wall, and intestinal tract are mentioned briefly. A 60 page chapter on diseases of the urinary tract attempts to cover urology with the result that many of the subjects of major importance to the gynecologist are dismissed with but a few words.

There is a short discussion of internal and external endometriosis with only a few inadequate lines on therapy. Sterility is covered well with extremely clear hysterosalpingograms and a good dissertation on examination of the semen. Contraception is also included in an excellent manner.

In the concluding chapters hormones, radiation and physiotherapy, diet, vitamins and hygiene of the female are given adequate discussions.

This voluminous text certainly covers the field of gynecology adequately with but few exceptions as noted. Subjects such as sterility, contraception, diet and vitamin therapy, and hygiene are welcome additions from the standpoint of the practitioner. This book is more worthwhile from this standpoint than the average. From the student's viewpoint, the lack of references and inadequate treatment of operative therapy are detrimental omissions. For anyone in the practice of medicine the color photographs deserve very favorable comment. If the photomicrographs and line drawings were up to their standard the book would be worthwhile from this standpoint alone.

J. DONALD WOODRUFF

In his book *Unipolar Lead Electrocardiography* Goldberger describes the newest variation in technique—the unipolar leads, originally developed in Wilson's laboratory in Ann Arbor, Michigan. The book is a brief monograph of theory and technique, modestly illustrated, and well indexed. It satisfactorily presents the author's concept of the new method, with his own variations.

The new method is presumed to offer new information by the electrocardiographic method of the position of the heart in the chest, rotation of the heart (clockwise and counterclockwise), bundle branch block, axis deviation, and ventricular hypertrophy. How practical and how necessary these are to the internists and cardiologists will be answered best by further experience.

CHARLOTTE C. MARKEE

THIS monograph *Essai de physiopathologie thyroïdienne: études cliniques, thérapeutiques et expérimentales* by Dr. Mahaux is sufficiently brief and well organized to serve as a guide for reviving European medicine and for his war-time graduates. It is scholarly enough to merit the approval of clinical investigators in the field of endocrinology in any country. The book comprises a few pages on fundamental studies of thyrostimulation in animals, a section on clinical studies of interrelated thyroid and pituitary disorders, and a larger portion which is devoted to the disorders and treatment of the thyroid gland itself. The sources quoted are international and well chosen. The opinions expressed, particularly with respect to the scope, advantages, and complications of the medical thyroinhibitors, are in accord with those of the best qualified American students in the field of thyroid diseases.

EDITH B. FARRINGTON

THE monograph of 206 pages *Retropubic Urinary Surgery* is of general value in drawing attention to the possibility of surgical approach by way of the space of Retzius. Millin states that his experience in the treatment of vesical neck obstruction by means of suprapubic (transvesical) perineal, or transurethral surgery has been, in the main, unsatisfactory and he was prompted to seek an improved method. He believes that the retropubic operation which he has devised and popularized answers the need for the improvement he was seeking.

The "cavum Retzii" as he calls it, has been voided by most surgeons in developing a technique for suprapubic operative procedures. Millin believes that when adequate drainage is provided the retropubic space is no more vulnerable to persistent in-

UNIPOLAR LEAD ELECTROCARDIOGRAPHY: THEORY AND LEADS, UNIPOLAR EXTREMITY LEADS AND MULTIPLE UNIPOLAR PRECORDIAL LEADS. By EUGENE GOLDBERGER, D.S., M.D. Philadelphia: Lea & Febiger, 1947.

ESSAI DE PHYSIOPATHOLOGIE THYROIDIENNE: ETUDES CLINIQUES, THERAPEUTIQUES ET EXPERIMENTALES. By Jacques MAHAUX. Paris: Masson & Co, Editeurs: Librairie Médicale, 1947.

RETROPUBIC URINARY SURGERY. By THOMAS MILLIN, M.A., M.Ch. (Dub.) F.R.C.S. F.R.C.S.I. Baltimore: The Williams & Wilkins Co., 1947.

FOR many years cardiologists were content with three limb leads as standard technique in recording electrocardiograms, as originally described by Einthoven. During the last decade chest leads were added and universally accepted.

fection than is the paravesical region. No persistent infection, no osteitis pubis or osteomyelitis of the pubis has been noted by him in any of his patients. He ascribes this complication to injury of the pubic periosteum although many instances of both osteitis pubis and osteomyelitis have been reported in this country following operations upon the bladder and prostate.

Millin recounts the experience of performing 375 prostatectomies since 1945 and his statistics surely indicate that his results have been as good or better than the average similar experience by skillful operators who utilize either the suprapubic or perineal approach.

He reviews the orthodox and accepted views of bladder neck pathology and deals conservatively with preoperative preparation and treatment. A series of brief case reports are included in a short chapter on fluid balance principles.

Millin stresses the ease with which the operation of retropubic prostatectomy can be performed if certain new instruments be described are used. Post operative complications are listed rather as possibilities than actual experience in Millin's series. He reports only one instance of major hemorrhage after operation and this is certainly a low incidence.

Millin lists other conditions as suitable for surgical treatment by the retropubic route, such as the fibrous and calculeous prostate, the malignant prostate and rupture of the posterior urethra. Strass incontinence in women is also treated by a rather complicated operation. The author states that he has performed this latter procedure in over 60 cases during the past 3 years with the most gratifying results. No amplification of this statement is given.

It seems questionable to accept Mr. Millin's enthusiasm in applying this operation to the fibrous prostate and other vesical neck obstructions of minor prostatic enlargements. Transurethral resection achieves an excellent result in these patients with less subjective upset. If Young's insistence, in carcinoma of the prostate on a total removal of the seminal vesicles and their related fascia is accepted as true and essential by advocates of radical perineal prostatectomy in America, Millin's procedure can not satisfy this criterion in carcinoma of the prostate.

Millin gives the impression of having a great personal enthusiasm for his work and undoubtedly has developed a most meticulous technique. He is a very skillful surgeon. The monograph gives the impression of having been compiled rather hurriedly and without the scientific, detailed case analyses which we would like to study.

Millin has undoubtedly made a valuable contribution to prostatic surgery. Time must elapse before a scientific evaluation of retropubic prostatectomy can be made. In the meantime many men will be operated upon by this method and large numbers of patients can be studied carefully so that the end results and late complications of these groups can be compared to similar groups treated by the suprapubic (transvesical) and the perineal routes. These two

latter methods, despite their drawbacks, have persistently been the routes of choice by most surgeons for more than a generation. VINCENT J. O'CONNOR.

THE text *Operative Gynecology*¹ by Crossen and Crossen has been revised and renewed extensively. Despite the alterations that have been made the present edition, the sixth, contains about 75 less pages than the fifth edition. Actually new operations and more illustrations have been added. Many of the historical notes on operations, which appeared in the earlier editions, have been deleted or condensed.

The section on radiotherapy is noteworthy in its discussion of the management of myoma uteri. Gratifying results can be obtained when great care is exercised in the selection of suitable cases for this type of treatment. With the recognition of definite indications and contraindications, irradiation therapy can prove to be a valuable addition to the gynecologist's surgical skills.

Prevention of carcinoma is emphasized and treatment of the diseased cervix is particularly stressed. Carcinoma *in situ* (intraepithelial carcinoma) is not mentioned or discussed. All gynecologists will not agree that the involuting uterus and ovaries should be removed in each case in which any one of the pelvic structures requires operation.

The chapters on anesthesia and the intestinal tract in relationship to gynecology have been well revised and rewritten by H. S. Brooks, Jr.

The volume has been carefully and thoroughly planned and well deserves to be a standard reference for the gynecologist. GEORGE A. HAYN.

THE book *Rheumatism and Soft Tissue Injuries*² by James Cyriax, deals with painful soft tissue lesions. Lesions of the fascia, bursae, tendons, muscles and ligaments, of obscure etiology and appearing for no obvious reason, have been classified under the rather broad term rheumatism. The author attempts to clarify the nature of these vague pathologic painful conditions by a system of diagnostic measures based upon clinical findings. The localization of the lesion to a definite tissue is based on a logical system of examination.

The book is divided into chapters dealing with various anatomic divisions of the body, with methods for examination of each part. Appropriate treatment, chiefly physical therapy, is discussed in detail for each lesion and part involved.

Many theories are advanced to explain obscure pathology and these may be accepted or rejected by the reader according to his views.

The book is well illustrated with line drawings and excellent photographs and should be of interest to physical therapists and those specialists dealing with the musculoskeletal system. WILLIAM A. LARMON.

¹OPERATIVE GYNECOLOGY. By Harry Sturgeon Crossen, M.D. and Robert James Crossen, M.D. 6th ed. St. Louis. The C. V. Mosby Co., 1948.

²RHEUMATISM AND SOFT TISSUE INJURIES. By James Cyriax, M.D. B.Ch. (Cantab.). New York and London: Paul B. Hoeber Inc., 1948.

A NEW edition of the well known and practical *Textbook of General Surgery*¹ has been brought up to date by the authors and nineteen collaborators and represents one of the finest textbooks available for the student of general surgery.

The subject matter emphasizes the fundamentals of physiology and pathology. There are many excellent illustrations of gross and microscopic pathology. The diagnosis and treatment of conditions encountered in the realm of general surgery are discussed in a manner both concise and adequate.

The material on nutritional requirements of surgical patients has been expanded in keeping with the growing interest in this field. There is an excellent chapter on surgical diseases of the chest. The section on war and catastrophe surgery has been rewritten and is a valuable chapter on military surgery.

For the most part surgical procedures are not described in too great detail, but this does not detract from the book's value as a text. The fundamental principles of surgical treatment are clearly defined and each chapter is terminated by a well chosen and up to date bibliography which affords an excellent reference list.

EDWARD W. GIBBS.

THE author's long experience in the radiology of the gastrointestinal tract gives him a peculiarly valuable preparation for the production of this reference and textbook on *The Digestive Tract in Roentgenology*². The text is complete. A very gratifying inclusion is a well selected list of references to the literature appended to each chapter. For the most part the illustrations are satisfactory. Some of the poorer illustrations are of rare cases in which the author had little choice. Careful perusal of this book impresses one with its value as a cyclopedic discussion of the subject of radiology connected with the digestive and biliary tracts. All things considered, this work probably rates as the best publication on radiology of the digestive tract in any language up to the present writing.

JAMES T. CASE.

THE author presents a simple clear easy to follow discussion in his book entitled *Coronary Heart Disease*³. In the introductory chapter he states that the progressive increase of this disease during the past 45 years has been the principal factor in the rise of heart disease to the leading place as a cause of death in this country. Ernestine continues with a general statement covering the difficulties of diagnosis which often arise followed by a brief but concise

discussion of the fundamental causes of the disease and the important changes in the electrocardiogram which corroborate a diagnosis.

The remaining chapters in the book are devoted to the principal clinical manifestations of coronary heart disease: angina pectoris, acute myocardial infarction, acute coronary failure, paroxysmal cardiac dyspnea (cardiac asthma), auriculoventricular and intraventricular block, other disturbances of cardiac rhythm and congestive heart failure. The conditions are clearly presented with their distinctive clinical picture or diagnostic changes in the electrocardiogram and the treatment of each as it differs in important respects from that of the other.

The discussion of each condition is clear, logical, and comprehensive in the limited number of pages. One very important feature is his free use of excellent references from the medical literature, chiefly of recent date. In addition his discussion of the use of various acceptable forms of treatment is highly adequate and should prove most helpful to the practitioner.

GEORGE C. TURNER.

THE increasing interest shown in respiratory physiology in its relationship to the application of inhalation therapy makes *Physiologic Therapy in Respiratory Diseases*⁴ particularly timely. A general review of anoxia and its treatment is followed by a practical application of these physiologic principles to the management of the most common conditions in which alterations of normal gaseous exchange occur. The interrelated use of aerosols and their role in the treatment of these pathologic processes is presented. Problems in aviation and war medicine are discussed and a practical, simple yet detailed description of the methods and apparatus for inhalation is presented. Contributions to the current literature in regard to apparatus and methods have been numerous and this compilation makes a valuable reference compendium to the subject, not only in recent developments but in such established apparatus as oxygen tents, masks, respirators, oxygen analyzers, etc. Clear illustrations, charts, and case histories, and chapter bibliographies add to the clarity of presented data. Of particular interest is the discussion of the equalizing pressure chamber and its role in the management of pulmonary tuberculosis, particularly in those cases hitherto classified as "hopeless."

Although this book is of special interest to the anesthesiologist, internist and surgeon it should be of value to those in all fields of medicine. There are few specialists who would not find something of practical interest in this book. It should be of broad interest to all practitioners.

EDWARD BIGG.

PHYSIOLOGIC THERAPY IN RESPIRATORY DISEASES. By ALVIN B. BERNHARD, M.D. 2nd ed. Philadelphia, London, and Montreal: J. B. Lippincott Co., 948.

TEXTBOOK OF GENERAL SURGERY. By WALTER H. COLE, M.D., F.A.C.S., and ROBERT ELLMAN, M.D., F.A.C.S. 5th ed. New York and London: D. Appleton Century Co., Inc. 948.

THE DIGESTIVE TRACT IN ROENTGENOLOGY. By Jacob BACKUS, M.D., Philadelphia, London, and Montreal: J. B. Lippincott Co., 948.

CORONARY HEART DISEASE. By A. CLOUTIER ERNESTINE, M.D. Springfield, Ill.: Charles C. Thomas, 948.

Osteotomy Lorenz, Self centering, 83
Ovary Preservation of function in cystic and sclerotic, report of 6 cases I single, 31 Results of treatment of carcinoma of with data on age incidence of this disease, 547

PAIN low back, acetab, Lumbosacral articulation roentgenologic and clinical study with special reference to narrow disc and lower lumbar displacement, 549 low back, acetab, Correlation of neurologic, orthopedic, and roentgenographic findings in displaced lumbosacral discs, 56

Pancreas, Translocation of pancreatic edema into pancreatic necrosis, 70 Celiac syndrome VII. Therapy of mesoconium ileus, report of 8 cases, with review of literature, 7

Parathyroid, Surgical aspects of hyperparathyroidism, review of 63 cases, 7

Patient, ambulatory bed, Reactions to morphine in, 5
Penicillin Treatment of empyema with topical and systemic, and their bactericidal agents, analysis of 40 cases, 44 Factors influencing mortality from acute perforated peptic ulcers, 85 Chemotherapy in peritonitis due to perforation of abdominal viscera, 440

Peptic ulcer Effect of tetra-ethyl ammonium chloride on gastric secretion and acidity in, 76 Factors influencing mortality from acute perforated, 85 Studies on vagotomy in treatment of III. Physiological aspect, 168 Re-evaluation of role of pyloric antrum in marginal, 5 Surgery in bleeding, urgent operation and principle of excision, 20 Place of surgery in emergency treatment of acute massive, upper gastrointestinal hemorrhage, 338 Studies on vagotomy in treatment of IV. Changes in gastric motility and effect of drugs on motility following complete vagotomy, 465 Vagotomy and Mann-Williamson ulcer, ed. 749

Peppy, Samuel, And so to bed, 551
Peritonitis, Chemotherapy in due to perforation of bicolonic, 44

Plasma, deficits, Blood volume and other determinations in preoperative and postoperative care, their practical applications in average hospital, 63

Plastics, Experimental approach to problem of increasing blood supply to lungs, preliminary observation on use of, 83

Pneumothorax, Present status of pulmonary resection in treatment of pulmonary tuberculosis, ed. 751

Portal vein, Portacaval shunts in treatment of portal hypertension analysis of 15 cases with special reference to suture type of end-to-side splenorenal anastomosis with splenectomy and preservation of kidney, 29 Portacaval anastomosis, 77

Pregnancy Childbearing in twilight of reproductive period, 45

Protholone, Studies on vagotomy in treatment of peptic ulcer IV. Changes in gastric motility and effect of drugs on motility following complete vagotomy, 465 Protein hydrolyte, Intravenous, subcutaneous and rapid intramuscular infusions of, 61

Pyloric antrum, Re-evaluation of role of, in marginal peptic ulcers, 23

RADIOACTIVITY Study of peripheral vascular disease with radioactive isotopes, part I, 2

Rectum, Intraluminal extension of carcinoma of descending colon, sigmoid, and rectosigmoid, pathologic study, 457 Evaluation of sulfathiazole and streptomycin as adjuncts in preparing large bowel for surgery, 576 Fecal continence following resections of various portions of, with preservation of anal sphincter, 669

Renal insufficiency Treatment of acute, 445
Reproduction, period of Childbearing in twilight of, 45
Richards, Linda, Diamond jubilee of professional nursing, ed. 623

Röntgen therapy Results of treatment of carcinoma of ovary with data on age incidence of this disease, 51
Tuberculosis of cervical lymph nodes, present surgical status, 719

Russell Sage Foundation Diamond jubilee of professional nursing, ed. 623

SHOCK, Intra-arterial transfusion, experimental and clinical considerations, 695

Shunts, Portacaval in treatment of portal hypertension, analysis of 5 cases with special reference to suture type of end-to-side splenorenal anastomosis with splenectomy and preservation of kidney, 29 Portacaval anastomosis, 77

Sigmoid, Intraluminal extension of carcinoma of descending colon and rectosigmoid, pathologic study, 457 Five year survival rate in cases of completely obstructing annular carcinoma of descending colon and pathologic study, 519 Fecal continence following resections of various portions of rectum with preservation of anal sphincter, 669

Skin, grafts, "Buried epidermis" graft, 68
Splenectomy, mimics, anal, Physiology of fecal continence, 280 Fecal continence following resections of various portions of rectum with preservation of 669; Method of repair for common type of traumatic incontinence of, 716

Spine, Lumbosacral articulation, roentgenologic and clinical study with special reference to narrow disc and lower lumbar displacement, 549 Correlation of neurologic, orthopedic, and roentgenographic findings in displaced lumbosacral discs, 561 vertebral column, Tumor of, 581

Spleen, excision, Portacaval shunts in treatment of portal hypertension analysis of 5 cases with special reference to suture type of end-to-side splenorenal anastomosis with splenectomy and preservation of kidney, 29

Stainless steel, Discussion of uses of metals in surgery and experimental study of use of airconium, 3

Stomach, pyloric, Surgical procedures employed and anatomical variations encountered in treatment of congenital pyloric, 585

Stomach, acidity secretion, Effect of tetra-ethyl ammonium chloride on gastric, in peptic ulcer, 76, Studies on vagotomy in treatment of peptic ulcer III. Physiological aspect, 168, Re-evaluation of role of pyloric antrum in marginal peptic ulcers, 23 excision, Surgery in bleeding peptic ulcer urgent operation and principle of excision, 20 Place of surgery in emergency treatment of acute massive, upper gastrointestinal hemorrhage, 338, Studies on vagotomy in treatment of peptic ulcer IV. Changes in gastric motility and effect of drugs on motility following complete vagotomy, 465 Carcinoma of validity of testing prognosis upon Borrmann typing or presence of metastases, 5131 Vagotomy and Mann-Williamson ulcer, ed. 749

Streptomycin Effect of, in experimental strangulation of bowel, 63 Chemotherapy in peritonitis due to perforation of abdominal viscera, 440 in surgery of pulmonary tuberculosis, 546 Evaluation of sulfathiazole and, as adjuncts in preparing large bowel for surgery, 576 Tuberculosis of cervical lymph nodes, present surgical status, 719 Present status of pulmonary resection in treatment of pulmonary tuberculosis, ed. 751

Sulfadiazine, Factors influencing mortality from acute perforated peptic ulcers, 85

- Sulfathiazidine, Evaluation of, and streptomycin as adjuncts in preparing large bowel for surgery 376
- Sulfonamides, Treatment of empyema with topical and systemic penicillin and other antibacterial agents, analysis of 30 cases, 24, Chemotherapy in peritonitis due to perforation of abdominal viscera, 440
- Surgery, plastic, "Buried epidermis graft, 68 preoperative and postoperative care, Intravenous, subcutaneous and rapid intramuscular infusions of "protein hydrolysate" 93 Blood volume and other determinations in preoperative and postoperative care, their practical applications in average hospital, 163 Discussion of uses of metals in, and experimental study of use of zirconium 313 emergency Place of, in treatment of acute massive, upper gastrointestinal hemorrhage 338, technique Critique of McVay operation for inguinal hernia, ed. 621 Technique of low thigh amputation 739
- Sympathectomy Effects of various types of upon vasomotor responses in hypertensive patients, 661
- TANTALUM**, Discussion of uses of metals in surgery and experimental study of use of zirconium, 313
- Tests, Cervical cytology key to diagnosis of early uterine cancer 197
- Thigh, Atraumatic low amputation further modification of and experiences with technique, 308 low amputation Technique of 739
- Thoracoplasty Present status of pulmonary resection in treatment of pulmonary tuberculosis, ed. 751
- Titanium, Discussion of uses of metals in surgery and experimental study of use of zirconium, 313
- Transfusion, intra-arterial, experimental and clinical considerations, 695
- Trochanter, see Femur
- Tuberculosis, of hip, Evolution and treatment of 357 Present status of pulmonary decortication ed. 478, pulmonary Streptomycin in surgery of 546 of cervical lymph nodes, present surgical status, 719 pulmonary Present status of pulmonary resection in treatment of ed. 751
- Tumor hemangioma, giant cell, chordoma, chondroma, fibrosarcoma, chondrosarcoma, osteogenic sarcoma myeloma, of vertebral column, 583
- Urethrocele with special reference to pubocervical fascia, 735
- Urethrocele, Surgical anatomy of cystocele and, with special reference to pubocervical fascia, 735
- Urinary tract, changes in cervical carcinoma 705
- Uterus cervix, cancer of Cervical cytology key to diagnosis of early 197 cancer of, Five year end results of irradiation therapy of at Memorial Hospital 343 Urinary tract changes in cervical carcinoma, 705
- VAGINA**, Bacteriology of In 75 normal young adults, 410 Surgical anatomy of cystocele and urethrocele with special reference to pubocervical fascia, 735
- Vagotomy Studies on In treatment of peptic ulcer III Physiological aspect 188 IV Changes in gastric motility and effect of drugs on motility following complete, 465 and Mann-Williamson ulcer ed. 749
- Vasospasm, Pattern of following acute arterial and venous occlusions, micrometric study 641
- Veins, anastomosis, Portacaval shunts in treatment of portal hypertension, analysis of 15 cases with special reference to suture type of end to-side splenorenal anastomosis with splenectomy and preservation of kidney 129 Portacaval anastomosis, 277 Pattern of vasospasm following acute arterial and venous occlusions, micrometric study, 641 portal, Studies on Eck fistulas in dogs, simple technique for preparation of portacaval anastomosis with aid of clamp 735
- Vena cava, Portacaval shunts in treatment of portal hypertension analysis of 15 cases with special reference to suture type of end to-side splenorenal anastomosis with splenectomy and preservation of kidney 129, Portacaval anastomosis, 277 Studies on Eck fistulas in dogs, simple technique for preparation of portacaval anastomosis with aid of clamp, 735
- Vertebra, Intervertebral disc, lumbar Lumbosacral articulation roentgenologic and clinical study with special reference to narrow disc and lower lumbar displacement, 549 Intervertebral disc, Correlation of neurologic, orthopedic, and roentgenographic findings in displaced, 561 Tumors of vertebral column 583

COLLECTIVE REVIEW

Historical Aspects of Penetrating Wounds of the Abdomen. FRANK L. LORIA, M.D. F.A.C.S.
New Orleans, Louisiana

521

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

- Head**
Plain Radiography of the Skull in the Diagnosis of Intracranial Tumors. DAVID STEINHOUSE 602
- Eye**
Congenital Impatency of the Nasolacrimal Duct. Du PONT GUERRY III and EDWIN L. KENNEDY JR. 550
Fat Embolization Involving the Human Eye. MILO IL. FRITZ and MICHAEL J. HOGAN 550
General Treatment of Conjunctivitis. RAUL ARTURO CHAVIRA 551
DeLig's Operation for Trachomatous Pannus. N. FOXES 551
Degeneration and Regeneration of Nerves in Corneal Transplantation: an Experimental Study. HUMBERTO ESCAPINI 551
Anterior Lentiglobus. An Atypical Case. E. SEX 551
The Capsular Complications of Cataract Extraction. CHARLES GOULDEV 552
Amblyopia ex Anopia. A New Concept of Its Mechanism and Treatment. B. M. LAKICH 552
Glaucomas. PETER C. KRONFELD and H. ISABELLE MCGARRY 552
- Ear**
Some Clinical Phenomena of Deafness in the Light of New and Old Tests of the Ear. F. KOBRAS 553
Auriculomastoid Tube Pedicle for Otoplasty. DAN N. STEFFANOFF 559
- Nose and Sinuses**
Intranasal Extension of Sellar and Parasellar Neoplasms. STANTON A. FRIEDBERG 553
Benign Cysts of the Antrum, Originating from the Jaw or Teeth. W. A. NEWLANDS 554
- Mouth**
Langer's Lines and Facial Scars. LEONARD R. RUBIN 554
- Neck**
Proteolytic Activity in the Physiology, Pathology and Therapeutics of the Thyroid Gland. Van Meter Prize Essay. E. DR. ROBERTS 554

- The Effect of Sex Steroids on Experimental Goiter and Iodine Storage in the Thyroid. F. X. GASSNER, H. W. BARRITT and R. G. GUNTAYSON 555
- The Parathyroid: A Study Based in Part, on 60 Post mortem Examinations with Presentation of a Case of Hyperfunctioning Adenoma. HACK U. STEPHENSON JR., WILLIAM L. McNAMARA, and BURNELL GOLDENBERG 609

SURGERY OF THE NERVOUS SYSTEM

- Brain and Its Coverings. Cranial Nerves**
Intracranial Aneurysm of the Internal Carotid Operation. Cure. GERMÁN HUGO DICKEMAN, LEÓN ZINDMAN and ALFREDO M. ZELASCO 556
Cerebellar Abscess, Acute, Otogenic. N. ANDERSON 556
Pinealomas. JOSE BENAIM 556
Diploic Epidermoid and Extradural Pneumatocele. Cranial Defects and Deformity. JOSEPH E. J. KIDO 557
Cerebral Angiography. JOHN R. GREEN and ROMAN ARANA 601
- Peripheral Nerves**
Cervicobrachial Pain. G. E. HAGGART 557
- Sympathetic Nerves**
Raynaud's Phenomenon and Atypical Causalgia: the Role of Sympathectomy. LEROY J. KLEINSANDEZ 557
- Miscellaneous**
Degeneration and Regeneration of Nerves in Corneal Transplantation: an Experimental Study. HUMBERTO ESCAPINI 551
Myocardial Infarction Resulting from Surgical Removal of the Stellate Ganglion in Angina Pectoris. D. DANIELOPOLOU 558
Chorea Gravidarum: Review of the Recent Literature and Report of 5 Cases. THOMAS W. McELIN, SIM B. LOVELADY and HENRY W. WOLTMAN 578

SURGERY OF THE THORAX

Chest Wall and Breast	
Present Day Criteria for Treatment of Breast Cancer ANTONIO PRUDENTE	559
Complementary Postoperative Radiotherapy for Breast Cancer GIANCARLO PERLAICA	606
Trachea, Lungs, and Pleura	
Bronchial Lavage. BERNI NOCTO	559
Tracheobronchial Tuberculosis. MAXUEL ROOMFOUR DUTRA	560
Wet Lung—An Experimental Study. ROLLIN A. D. VIEL, JR., and WILLIAM R. CATE, JR.	560
Pneumothorax Due to Talk in the Cosmetic Industry NATHAN MILLMAN	56
Cytus Inversus, Bronchiectasis, and Cystitis—the Kartagener Syndrome. Report of Cases. JUAN MARTIN ALLESTRE and LILIANO LANOIR	56
Cancer of the Lung in the Female. ANDREA A. SANTAS	56
Carcinoma of the Lung. Factors Affecting Survival after Resection of Cancer of the Lung. RALPH ADAMS	563
Acute Postperforal Mastitis. H. CLOER HEMELTIN, CHARLES G. FREUDENBERG, and K. EILEEN HITE.	579

Heart and Pericardium

Myocardial Infarction Resulting from Surgical Re- moval of the Stellate Ganglion in Angina Pre- toris. D. DANIELOPOLO	558
Cardiac Resuscitation. ROBERT D. DRIPPS, CHARLES K. KIRBY, JULIAN JONASOV, and WILLIAM H. EHR	597
Radiology in Heart Surgery. T. HOLMES SELLORS	603

Esophagus and Mediastinum

On the Pathogenesis and Surgical Treatment of Esophageal Diverticula. L. PIERA LÓPEZ	563
The Treatment of Carcinoma of the Esophagus and Cardiac End of the Stomach by Surgical Lateral- tion. RICHARD H. SWEET	563
Cancer of the Cervical Esophagus. WILLIAM L. WAY- SON and JOHN L. POOL	563
Seven Resections of the Thoracic Esophagus for Car- cinoma, with Esophago-Gastric Anastomosis, followed by Operative Cure. ALAIN MOCCHET and PAUL ORSINI	564
Surgery of the Thoracic Esophagus. F. D. ALLARDIS and CH. DUBOIS	565
Acute Posterior Mediastinitis from Per-Oral Wounds of the Esophagus. RAOUÏ JOUCOURRET	565

Miscellaneous

Cardioesophageal Cancers Treated via the Trans- thoracic and Transdiaphragmatic Route. FELIX DE AMERETI and ELISEO OTAZA	567
--	-----

SURGERY OF THE ABDOMEN

Historical Aspects of Penetrating Wounds of the Abdomen. Collective Review. FRANK L. LORIA, M.D. F.A.C.S., New Orleans, Louisiana	561
Abdominal Wall and Peritoneum	
Chronic Eventrations and Voluminous Herniations. Preparation by Progressive Pneumoperitoneum. IVÁN GOTT MORALES	566
Mesenteric Thrombosis. J. E. MCCLEMMAN and BERNARD FISHER	566
Gastrointestinal Tract	
Seven Resections of the Thoracic Esophagus for Car- cinoma, with Esophago-Gastric Anastomosis, followed by Operative Cure. ALAIN MOCCHET and PAUL ORSINI	564
Cardioesophageal Cancers Treated via the Trans- thoracic and Transdiaphragmatic Route. FELIX DE AMERETI and ELISEO OTAZA	567
The Roentgen Diagnosis of Cancer of the Cardiac Region of the Stomach. ROBERT S. SUTTERMAN	567
Surgical Treatment of Cancer of the Gastric Cardia. GEORGE T. PAGE and GORDON McNAUL	568
Transthoracic Gastric Resection for Lesions of the Cardia of the Stomach and Lower Part of the Esophagus. JOHN H. PAYNE and O. THORON CLAGETT	568
Perforated Gastric and Duodenal Ulcers. Statis- tics on 95 Observations. P. LARGHERIO VARRI, L. M. BOSCH DEL MARCO, L. ALFONSO, and F. GIULIA	568
Pathologic Perforation of the Neoplastic Colon. JULIO V. URIBES	568
Tuberculosis of the Appendix. PASQUALE FICARA and UGO PAOLANTONIO	569
Sulfonamide Therapy and Abolition of Drainage in Perforative Appendicitis with Purulent Peri- tonitis. PABLO STEFANIK and PASQUALE FICARA	569
Ureteroigmoid Anastomosis. F. CASTANO, A. B. ORTIZ, and J. P. TORRESA	569
Liver Gall Bladder, Pancreas, and Spleen	
Clinical Studies of Liver Function. The Hepatorenal Syndrome. C. ROBERT SCHMIDT and V. E. CHERRY	570
Anorexia and the Liver with Special Reference to Shock and Chronic Malnutrition. J. GILLMAN and T. GILLMAN	570
The Differential Diagnosis of Jaundice. S. ALLEN WILKINSON	571
Studies on the Pressures Within the Common Bile Duct. RAIMO S. FERRACANI	571
The Effect of the Ligation of the Pancreatic Ducts and of Pancreatectomy after Duct Ligation on Serum Lipase. MARTIN M. NOTEMAN, T. DEN- NIS PRATT, and JOSEPH BERUTTI	571
Carcinoma of the Pancreas. Diagnostic Criteria. GRAYSON F. DASHBELL and WALTER LINCOLN PALMER	572
Surgical Conditions of the Spleen. FRANK H. LANEY	573

INTERNATIONAL ABSTRACTS OF SURGERY

GYNECOLOGY

- Uterus**
 Uterine Cancer Its Early Detection by Simple Screening Methods DANIEL J. McSWENNEY and DONALD G. MCKAY
 Sarcoma of the Uterus THOMAS PERRY JR
 Additional Data in the Technique of Vaginal Hysterectomy N. SPROAT HEANEY

574
 574
 574

Miscellaneous

- Therapeutic Abortion Medical Considerations. HORACE M. KORN 580
 Therapeutic Abortion Surgical Considerations. SAMUEL C. HARVEY 580
 A Simplified Method of Roentgen Pelvicephalometry ANGUS K. WILSON 603

GENITOURINARY SURGERY

- Adrenal, Kidney and Ureter**
 Implantation of the Ureters into the Recto-Sigmoid in Case of Urethrovaginal Fistula. ANGELO DE PALO 576
 Renal Infarction FRANCIS C. REGAN and E. GRANVILLE CRATCHEY 581
 Renal Tuberculosis JAMES C. McCLELLAND, KENNETH H. DAVIS, and ERIC MASSIO 582
 Aneurysm of the Renal Artery PEDRO MORREYRA, BERMAN, and ALBERTO HALAC 582
 Renal Rickets and Polycystic Disease. HERMAN L. KRETZSCHMER 583
 Adenocarcinoma and Tuberculosis of the Same Kidney HAROLD A. NEUBLING and WALTER WALTON 584
 Uretersigmoid Anastomosis. E. CASTANO A. B. ORTIZ, and J. P. TORRORA 584
 Renal Osteodystrophy in the Adult. JOSE VALLS, FRITZ SCHAJOWITZ, and CARLOS DELBUX 589
 Kidney Complications during Sulfonamide Therapy A. HARRISTUP ANDERSEN and IS. ANDERSEN 608
 Renal Transplantation Anastomosis with Nonmetallic Prosthesis. JACQUES OUDOT 610

OBSTETRICS

- Pregnancy and Its Complications**
 Hemocoagulation in Obstetrics. LUIS TISNÉ BROUSSE and ORLANDO TRIVELLI ROCCO 577
 Pernicious Anemia of Pregnancy and the Puerperium. L. S. P. DAVIDSON R. H. GIRDWOOD and J. R. CLARK 577
 Leucemia and Pregnancy JOHN A. WILLIAMS 577
 The Possible Significance of Arterial Visualization in the Diagnosis of Placenta Previa. LEO J. HART 578
 Thrombosis Gravidarum Review of the Recent Literature and Report of 5 Cases. THOMAS W. McELIN SIM B. LOVELAND and HENRY W. WOLTMAN 578

- Bladder, Urethra, and Penis**
 Construction of Terminal Urethra in Hypospadias JOSEPH H. KRIEGER 585
Genital Organs
 The Prostatectomy of Terence Millin—the Operation of the Future. H. DUVEROY 586
 Rationale and Results in Retropubic Prostatectomy OWSELBY GRANT and ROBERT LICH, JR 587

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

- Conditions of the Bones, Joints, Muscles, Tendons, Etc.**
 Renal Osteodystrophy in the Adult. JOSE VALLS, FRITZ SCHAJOWITZ, and CARLOS DELBUX 589
 Osteoarthritis of the Cervicodorsal Spine (Radiculitis) Stimulating Coronary Artery Disease. DAVID DAVIS and MAX RITVO 589
 Symmetrical Equal Bilateral Epiphyseal Separation of the Distal Radial Epiphysis PASQUALE FIGARA 579
 Low Radio-Ulnar Dyschondroplasia or Madelung's Disease. ALBERTO INCLÁN COSTA 589
 Osteochondritis Dissecans of the Hip JOSE VALLS and DOMINGO T. MÚSCOLO 590
 Popliteal Hygromas. LEONICIO LUIS FERNÁNDEZ 590

- Labor and Its Complications**
 The Duration of Labor Mean, Median and Mode TRENT BUSBY 578
 The Treatment of Placenta Previa. JORGE ROUBIL LARD GONZALEZ 579
 Anal (Saddle Block) Anesthesia in Obstetrics. G. J. ANDERSON, WILLIAM J. DIECKMANN P. OUDA, H. D. PRIDDLE, and Others 579

- Puerperium and Its Complications**
 Puerperal Mastitis. H. CLOSE HESSELTINE, CHARLES G. FREUNDLICH and K. EILSEN HITE 579

Surgery of the Bones, Joints, Muscles, Tendons, Etc.	Regulation of Blood Pressure during Spinal Anesthesia. Observations on Intramuscular Pressure and Skin Temperature. H. MILWIDSKY and A. DE VRIES	599
The Bridging of the Bone Defects. A. GIBSON and B. LORAM		597
Fractures and Dislocations	Blood Transfusion	
Primary Closure of Compound-Fracture Wounds. With Immediate Internal Fixation, Immediate Skin Graft, and Compression Dressings. ARTHUR G. DAVIS	Hemoconcentration I. Obstetrics. LUIS TIRRE BROUHA and ORLANDO TRIVELLI ROSSI	577
The Management of Compound Dislocations. JAMES K. STACE and PAUL MILLIGAN	Perilous Anemia of Pregnancy and the Puerperium. L. S. P. DAVIDSON, R. H. GRAYWOOD, and J. R. CLARK	577
The Magnusson-Stack Procedure for Recurrent Dislocations of the Shoulder. N. J. GIANCOTTAS	Leucemia and Pregnancy. JOHN A. WILLIAMS	577
Mechanism of Fracture of the Carpal Scaphoid. HECTOR DAL LAO	Acute Hematogenous Osteomyelitis. A Study of Treatment. WILLIAM NACHLAS and HENRY R. MARKHUSE	594
High Fractures of the Fibula. H. JACKSON BROWN	The Effect of Radiation on Hemopoiesis. Is There an Indirect Effect? JOHN S. LAWRENCE, WILLIAM N. VALDEGUTER, and ANDREW H. DOWDY	605
Segmental Arterial Spasm Associated with Supracondylar Fracture of the Elbow. Report of a Case. A. DALE COMBIE	Some Hematologic Effects of Irradiation. WILLIAM BLOOM and LEON O. JACOBSON	605
Orthopedics in General	The Value of Patchet Counts in Radiotherapy. W. M. LOUET BROWN	605
Acute Circulatory Failure in an Injured Limb. D. L. GRIFFITHS	Thrombin and Delayed Thrombin, Modifiers of the Coagulation Time. MICHAEL DRECHTNER, GEORGES CAET, and MICHAEL GOURARIET	607
Acute Hematogenous Osteomyelitis. A Study of Treatment. WILLIAM NACHLAS and HENRY R. MARKHUSE		
The Surgical Treatment of Intractable Plantar Warts. JAMES A. DICKSON		
	SURGICAL TECHNIQUE	
	Operative Surgery and Technique; Postoperative Treatment	
	Anesthesia following Surgical Procedures. DANIEL C. ELLIS	594
	Cardiac Resuscitation. ROBERT D. DUFFIN, CHARLES K. KIRBY, JULIAN JOHNSON, and WILLIAM H. ELLIS	597

COLLECTIVE REVIEW

HISTORICAL ASPECTS OF PENETRATING WOUNDS OF THE ABDOMEN

FRANK L. LORIA B.S. M.D., F.A.C.S., New Orleans, Louisiana

SINCE prehistoric times the abdominal cavity has been looked upon as one of the most vulnerable regions of the body and injuries involving it have always been considered very serious. The lethal character of a wound which opened the abdomen was well known to the ancients. Not infrequently the military surgeons or in their absence, the war chiefs or commanders serving as surgeons were required to remove arrows or spears implanted into the abdomen or if these did not pass entirely through the cavity to pull them through the opposite side. Usually unsuccessful efforts were exerted to remove inaccessible arrowheads from the cavity by the use of drawing plasters. The Ionian Greeks referred to the physician as the *hypoos* meaning an extractor of arrows.

From the Homeric epics we learn of the death of Polydorus (13) at the hands of Achilles, whose weapon on entering the back of Priam's son made its exit in front, and the victim bending clasped his bowels in his hands and while Troas (14) begged for his life, Achilles thrust

His sword into his side the liver came
Forth at the wound the dark blood gushing filled
The Phrygian's bosom

We learn also of Eurymachus (16) who succumbed to the effects of a liver wound which was inflicted by an arrow from the powerful bow of Odysseus.

From the Department of Surgery Tulane University School of Medicine, and the Charity Hospital of Louisiana at New Orleans.

Hippocrates (1) postulates that a severe wound of the bladder of the small intestines of the stomach and of the liver is deadly. Xenophon (112) in his *Anabasis*, speaks of a Greek captain who after being wounded made his way back to camp holding his bowels in his hands. Every indication points to a number of abdominal wounds among the twenty three inflicted, suffered by Julius Caesar (15) at the hands of his numerous assassins.

Although murder by stabbing was chiefly superseded by poisoning during the Dark Ages nevertheless, the dagger arrow lance, spear, and sword continued to account for many frequently fatal penetrating wounds of the abdomen. The 'Age of the Despots' in Italy is replete with assassinations in which the dagger was usually the principal weapon used. Galeazzo Maria (103) Duke of Milan in 1476 died immediately as the result of almost simultaneous stab wounds of the back chest, and abdomen.

The self-disembowelment of the Japanese, known as *hara kiri* (26) is a vestige of old feudal Japan which has come down as a 'national form of honorable suicide'. After the preliminaries in the ritual the suicide plunges a dagger into the left side of his abdomen below the costal margin draws it slowly across to the right, and finally turns it up giving a sharp upward cut. This procedure is looked upon as wiping out all dishonor—a thought not foreign to our present day Western civilization—and probably a means of facessaving so important to the Japanese mental complex.

INTRODUCTION OF GUNPOWDER AND FIREARMS

Although 1354 is given as the year in which gunpowder was introduced in Europe by Schwartz (27) it is very likely that gunpowder was known to the Europeans long before this time, as powder works are described at Augsburg in 1340 and gunpowder was known in Florence as early as 1326. The early and very crude firearms, the first invention of which is attributed to Schwartz, no doubt appeared soon after the introduction of gunpowder. Certainly at the battle of Cressy (84) in 1346 the bowmen were arranged in such a way as to have small bombards between them which with fire threw little iron balls to frighten the horses." Louis XI of France (1477) used bombards of great length and power some with stone balls and some with iron. Wounds inflicted with such primitive firearms were very probably in the nature of bruises or contusions, very few possibly ever penetrating the surface of the body.

The pistol, which was the predecessor to the modern revolver and automatic, is said to have been invented in Pistola, Italy probably between 1475 and 1500. The revolver an improvement over the two and three barreled pistols, made its appearance early in the seventeenth century while the first automatic was introduced in 1803. Since the invention of these three weapons the greatest number of gunshot wounds of the abdomen in civilian life is traceable to them. The old musket and its descendants, the shotgun and rifle, as well as the highly efficient machine gun (so commonly used by gangsters in this country in the twenties and early thirties) are relatively infrequently used in civilian life as a means of assassination. In military undertakings today the revolver and automatic probably cause fewer abdominal injuries than the rifle, machine gun, hand grenades, shrapnel, splinters of shells and bombs, and fragments from other contrivances. Each new weapon introduced has been featured by an increased velocity of the missile used, and each has been devised for a more certain and greater destruction of the object struck. From all indications, therefore, probably very few if any penetrating abdominal gunshot injuries were seen before 1400 and since then they have not only been on the increase but the wounds inflicted have been of the more disastrous types—this in spite of an improvement lately reported in the mortality rate among the victims of these injuries (22, 23, 40, 47, 63, 80, 91, 93, 100).

The introduction of firearms made available a means of assassination in which the assailant was relatively free from the possibility of injury at the hands of the victim, an immunity which he

did not fully enjoy in assassination by stabbing, especially if the intended victim was larger and stronger than the assailant. However the introduction of firearms did not eliminate homicide by stabbing. Lances, swords, and daggers continued to enjoy their ancient popularity. Arrows with their bows became obsolete in Europe shortly after the invention of firearms. Spears very probably gave way to the bows and arrows many years before the introduction of gunpowder and the dagger is still with us. Stab wounds today however are usually inflicted with large knives of various types or ice picks which have relatively recently become very popular. At the New Orleans Charity Hospital there were admitted—during the 15 years prior to January 1, 1941—478 cases of penetrating abdominal gunshot wounds, 85 per cent of which were due to revolver shots, and 330 cases of penetrating stab wounds of the abdomen, the majority of which were inflicted with various types of knives.

EARLY TREATMENT OF PENETRATING ABDOMINAL WOUNDS

The ancients usually washed all wounds carefully with warm water after which they were examined more thoroughly. Wine was given as a stimulant. Spears and arrows were withdrawn or excised. The wound was treated further with oil or wine, or with root juices, and was protected with a woolen dressing. Certain herbs, known to relieve pain, were used freely, and the wounded were kept at rest in tents. Early in the Dark Ages there began the custom of using boiling oil and hot irons in the treatment of wounds. To these were added greasy salves and plasters. This abominable and barbarous treatment was finally stopped by Ambrose Paré (1510-1590) when he accidentally ran short of oil and thus discovered that other much less painful and less barbaric methods were not only more comfortable, but likewise more beneficial. In the treatment of gunshot wounds, which were becoming fairly common injuries by this time, Paré introduced the practice of searching for the ball, using "large and deep incisions" (43) if necessary.

That the problems connected with the proper management of penetrating abdominal wounds were difficult is attested to by the following recommendations by Jerome of Bruynswyke (13) who in 1525 taught

"When the guttes is wounded oerthwart or in pecis, than it is dedly: yf it be lengthe woundyd, it may be holpen. If that the wounde of the belly is not grete knowgh, than shall ye make it greater

as I shall shewe you hereafter than shall you take out properly the guttes, and sow it thereafter as it is needful with a skynners nedyll. Jamericus Theodonius Rogerius lay elder pypes in the guttes under the seme, that the same rotte not. Whilhelmus and some other lay there in a part of a cryer of a throte goll of a beest, as the IV maysters sayth. But Lanfrancus and Guido they thinke it not be profytable for that nature is inclined to outdrawinge strange thyngys, and thus yt belpt not therefore it was layd, and it is better that the guttes be sowyd as afore is sayd and that it be clensyd of the unclenes.

For very obvious reasons these recommendations were soon forgotten and the treatment of penetrating wounds of the abdomen became very conservative. Hence, from about the middle of the sixteenth century to well on in the nineteenth century when Sims and others began recommending intervention in cases of penetrating wounds of the abdomen—especially those caused by fire arms—these injuries were treated by rest, opium dressings, and protection of the wound with wine or brandy as stimulants and frequent bleedings or venesections. Some feeding by mouth was at times allowed but most usually small quantities of liquid foods were administered by rectum. In addition Guthrie mentions the use of leeches, fomentations to the belly, calomel, blistering of the abdomen, and the judicious use of purgatives.

Venesections for bleeding or the practice of bloodletting (as this procedure was more commonly known) and the extensive use of leeches about inflammatory areas, were therapeutic measures enjoying great popularity up to perhaps 100 years ago. After a rather lengthy dissertation Guthrie explains that 'when great inflammatory fever or inflammation come on either of which is a great increase in action the patient can bear it for several days without any permanent detriment, provided he lose blood in proportion to the increase of action, in order to prevent its destroying the texture or function of any vital part. If this be not done, the patient must be very soon carried off because the action will increase so rapidly as to be soon incompatible with life, unless relief be obtained. The amount of blood to be removed usually depended upon the time that relief from pain occurred during the treatment by this bloodletting. Ordinarily the removal of from 12 to 25 ounces was recommended.

The practice of probing penetrating wounds very probably dates from antiquity. When fire-

Fig. 1. Ambroise Paré (1510-1590) "father of modern surgery" (at 75) who introduced many new practices in the military surgery of his time including the use of the ligature to control hemorrhage instead of hot oil and the cautery (Ambroise Paré and His Times, 1510-1590, by Stephen Paget. New York and London G. P. Putnam's Sons, 1897)

arms were improved to the point of producing penetrating wounds the attendants placed much importance on probing to remove the missile, if possible. Later in addition to determining the location of the bullet for its possible removal, the probe was used to trace its course. In this way a more accurate diagnosis of the structures or viscera injured was considered likely. The use of the probe as a diagnostic instrument continued until the very early years of the present century when the practice was condemned as dangerous.

LATER TREATMENT

The ultraconservatism practiced in the management of penetrating abdominal injuries continued practically unchanged until Sims began emphasizing the need for laparotomy to repair the damaged structures in these cases, particularly in gunshot wounds. Prior to this, Baudens suggested bold operations in some cases of penetrating

Fig. 2. James Marion Sims (1813-1883). American surgeon. Strong advocate of surgical intervention in penetrating gunshot wounds of the abdomen. ("Surgery of Abdominal Wounds," in Hamilton Bailey, A. (Ed.), The W. B. Saunders Co., 1944.)

gunshot wounds of the abdomen, having performed enterorrhaphy in 2 cases of abdominal gunshot injuries during the French Algerian War 1830 (98) after which one of his patients recovered. Baudens, accordingly, enjoys the distinction of probably having been the first to perform laparotomy for penetrating abdominal gunshot wounds. During the Crimean War this surgeon advised the introduction of the finger or a small sponge through the enlarged penetrating abdominal wound to determine the presence or absence of blood, feces, or bubbles of gas (67) in the absence of which he recommended abstention.

It was not very long before the views of Sims, the leader of the interventionist movement in the treatment of penetrating abdominal gunshot wounds, were upheld by many other surgeons, particularly in America and Germany. The leader of the abstentionist group, which was particularly strong in France, was Réclus (83) whose experiments on dogs and whose report of 66 recoveries in a series of 88 abdominal wounds treated conservatively were especially convincing to his followers. He advised laparotomy only in those cases in which the signs of visceral injury were unmistakable. However the writer believes that Réclus convincingly favorable results were possible because of the much smaller caliber of the missiles used in the French guns of that day whereas, the

guns in America, Germany, and England were probably of a larger caliber and the bullets, therefore, very likely produced much more damage to the tissues involved.

A symposium on penetrating abdominal gunshot wounds, held by the American Surgical Association in May 1887, concluded with the consensus of opinion in favor of the operative treatment, even in those cases in which the diagnosis of injury to important intraperitoneal structures was in doubt. At this meeting Nancréde a splendid paper covered the subject of laparotomy excellently. In spite of losing 2 of his 3 patients, it was his opinion that the advantages of operation are manifold. On the same day case reports by Kinloch, who is credited with having operated upon the first penetrating abdominal gunshot injury in this country, and by Keen, were followed by a general discussion with additional illustrative case reports of penetrating gunshot and stab wounds by Conner Gunn, Edwin Richardson (who reported from the New Orleans Charity Hospital), Agnew, (who had been a consultant in the gunshot wound case of President James A. Garfield), Llandridge, Ransohoff, and Roberts. In his paper Kinloch quoted statistics by T. S. K. Morton, in which the latter (after a careful study of the world literature) gave reports of 57 cases operated upon for abdominal trauma up to that time (January 26, 1887). Among these there were 22 gunshot wound cases with 17 deaths—a mortality rate of 77.2 per cent. Kinloch further points out that Walter performed the first abdominal section for "traumatism" in America followed by his first case in 1863. Walter's case was that of a 22-year-old blacksmith who was kicked over the pulvis while in a fight. Because of excruciating pain exploration was advised. This was done in January 1850, several days after the fight. A urinary bladder laceration 2 inches long was found. Urine and blood were removed from the peritoneal cavity. A retention catheter was placed in the bladder and kept there 3 weeks. The patient recovered.

In an editorial entitled "Laparotomy in Gunshot Wounds of the Abdomen" (24) appearing in the Journal of the American Medical Association on January 12, 1889, the subject was reviewed very thoroughly and the opinions of the various writers of that day were given. After consideration of the recommendations of Réclus, in which the noted French surgeon advised (1) firm compression of the abdomen to check hemorrhage and fecal extravasation, (2) administration of large doses of opium, and (3), failing in this, laparotomy—the editorial concluded by giving the impression that its writer was in total disagreement

with Réclus on several points, and took the stand that intervention is almost invariably to be preferred to passive treatment in these cases.

Despite the trend of surgical opinion in America the results, following the adoption of the active or operative treatment, were for many years practically no better than those following conservative treatment. Thus, in 1889 Barrow reported laparotomy in 4 cases with 1 recovery—a case in which no visceral nor other important structural injuries were found. Somewhat prior to this, Martin reported a mortality rate of 77.2 per cent. The tendency toward intervention was so convincing however that at the start of the Boer War (32) (1899-1902) the British advised laparotomy in all cases of penetrating abdominal wounds when there was reason to believe intestinal injury existed. However a study of the results shortly after the onset of hostilities showed that the mortality was greatest among the patients treated by laparotomy. Accordingly during the remainder of the war conservatism was the order of the day. This British military order remained in force through the early months of the first World War not being rescinded until 1915 at which time a study of the cases of penetrating abdominal wounds showed the need for intervention. It is believed that a smaller type of bullet used by the Boers in the South African War obviated the need for laparotomy in many cases of intestinal perforation inasmuch as the small openings produced were easily closed by the intestinal mucous membrane. However during World War I the larger missiles, as well as a greater and more damaging variety of them produced larger perforations and more extensive lacerations. These necessitated intervention if there was to be any hope of recovery.

During the Russo-Japanese War (1904-05) the policy of conservatism was soon replaced by one of intervention following the innovation by Princess Gedroitz (32) who organized and equipped a railway carriage operating unit in such proximity to the battle front that it was possible to operate on penetrating abdominal wounds within a period of three or four hours of their being sustained. The Russian Army authorities were in this way convinced of the great importance of time in these cases and advised continuation of this practice.

Thus the interesting indecision on the part of the Surgical World as regards active or passive treatment in penetrating wounds of the abdomen continued for 55 years. Early in the first World War the mortality in these cases was frightful. This represented the period of nonintervention in this conflict. Later however when the victims were treated and operated upon in the clearing

Fig. 3. Paul Réclus (1847-1914) French surgeon. Leader of the abstentionist group in the treatment of abdominal gunshot wounds. ("Surgery of Modern Warfare" by Hamilton Bailey. Baltimore: The Williams and Wilkins Co. 1944.)

stations nearer the front, the mortality dropped to around 56 per cent (208).

Although the matter of active or passive treatment in penetrating abdominal wounds occupied the attention of and appeared to be of paramount importance to surgeons for many years, not much was otherwise done in the management of these cases. Infusions of saline solution and glucose, although known, were rather infrequently used before the present century. The Matas (71) continuous intravenous drip of glucose, like the ordinary infusions of saline solution (68) and glucose has only relatively recently been used in these cases of trauma. These procedures have proved to be indispensable adjuvants in the treatment of patients with penetrating wounds of the abdomen.

As regards the operability or fitness of a patient with a penetrating abdominal gunshot wound for exploratory celiotomy the rule taught by Matas (70) in his military classes in 1916 in 1918 at the New Orleans Charity Hospital very probably applies as well today as it did then except that blood and especially plasma transfusions are now easily substituted for the saline-glucose-adrenaline continuous intravenous drip which was then used. His rule was that no surgical exploration should be undertaken until the patient shows signs of having reacted from shock.

Fig. 4. Diagrammatic sketch emphasizing the location of the large intrathoracic and intra-abdominal blood vessels, injury to any of which may result in sudden death.

In all cases of penetrating gunshot wounds in which the patients were brought to the hospital "in a state of collapse from shock or hemorrhage, or both" the first step was to deal immediately with the collapse by using the continuous saline-glucose-adrenaline intravenous drip, which Alatas first introduced in New Orleans in 1910 as an improvement over the massive repeated infusions (which were likewise first used by him in New Orleans in 1888) and as a substitute for the uncertainties of the Murphy rectal saline drip which had been in vogue in abdominal practice since the beginning of the century. While the intravenous drip was in progress, the usual other measures in the treatment of shock and collapse were applied, and all preparations were made for the exploration. However no incision was made until the patient showed signs of cardiovascular reaction to the stimulating and resuscitating effects of the warm saline-glucose-adrenaline drip infusion. With the first signs of returning animation, as shown by the color, temperature, pulse rate, blood pressure, consciousness, and pupillary reactions, the exploration was immediately undertaken in

the effort to control hemorrhage as the first indication. If the patient failed to react to the intravenous infusion, operation was considered useless "as shock was the preponderating feature of the collapse, and any added trauma would certainly precipitate a fatal issue on the operating table.

In the cases showing hemorrhage as "the dominant feature of the collapse" the pulse and general condition would improve with the increasing blood volume supplied by the infusion, and an exploration could then be performed while the drip was going on with the expectation at least of survival of the patient from the operation.

The first use of a blood transfusion in penetrating abdominal gunshot wounds is credited to Fonio in 1918, although he ascribes priority to Agote. The use of transfusions in abdominal trauma has saved many lives which would have certainly been lost previously. For a good many years, the problem of securing donors (60) as quickly as needed interfered materially with this form of therapy. The recent introduction of blood plasma for intravenous use in the treatment of shock and hemorrhage, and the establishment of plasma banks in most modern hospitals, has helped very considerably to solve this problem. At present, therefore, with the liberal supply of blood whole or citrated and blood plasma, all of which are usually on hand in every modernly equipped hospital, the stimulating and resuscitating effects of the transfusion are far more quickly perceptible than when simple artificial sera are used, particularly if the blood transfusion is kept up as a continuous intravenous drip of indefinite duration, sufficient at least to compensate for the volume of blood lost. If a patient on the operating table is too deeply shocked to respond to this fundamental mode of cardiovascular stimulation, an operative procedure will not only fail to save the victim but will more than likely precipitate the end. Thus, today in addition to undergoing laparotomy almost routinely in these cases, the victim receives the benefits of prompt and adequate preoperative preparation, postoperative care, especially as regards the replenishment of fluids, electrolytes, plasma and blood, the all important vitamin therapy so essential in convalescence, and, lately the benefits of chemotherapy (63) (93) (46) which appears to help very materially in reducing the mortality among these victims.

In connection with the preoperative and postoperative care of these patients, too, the continuous drainage of the gastrointestinal contents by siphonage through an indwelling gastroduodenal tube, introduced by the nasal route, has proved

J. J. J. J. J.

Fig. 5. Diagrammatic sketch emphasizing the relationship of the relatively more superficial anterior structures of the chest and abdominal cavities.

to be very valuable and indispensable. Nothing else in the surgeon's armamentarium is as effective in controlling vomiting and tympanites. Probably no other advance has contributed more materially to the comfort of these patients than this procedure, which was first introduced in the New Orleans Charity Hospital simultaneously with continuous intravenous drip by Matas in 1911 (71) in the treatment of intestinal obstruction. This same procedure, modified in 1931 (107) by the use of a suction apparatus for simple siphonage, is now known as the Wangenstein suction.

DIAGNOSIS IN ABDOMINAL TRAUMA

The introduction of the operative method of treating abdominal trauma particularly penetrating wounds of this cavity by Baudens in 1830 automatically created a great need for a more careful and more accurate diagnosis in all cases of trauma to the abdomen. For many years, the probe was one of the most important instruments in the surgeon's armamentarium. With it the course of a penetrating missile could more or less be traced. The use of this instrument as a diagnostic measure was considered good practice until

do not illustrate the
(where shown anterior)

Fig. 6. Diagrammatic sketch emphasizing the positions of the retroperitoneal structures and the peritoneal cavity. Kidneys, ureters, adrenals, and duodenum are the structures more frequently injured, especially by penetrating abdominal gunshot wounds.

early in the present century, when many of its dangers were emphasized and its popularity consequently faded. Because of their conspicuousness, the entrance and exit points in penetrating or perforating wounds of the abdomen attracted attention from the earliest days. Extensive stab wounds especially those in which the weapon perforating the cavity showed itself on the opposite side, were easy to diagnose with respect to involvement of the abdomen. Smaller stab wounds were more difficult to diagnose as regards involvement of the cavity and its contents. It was in this type particularly that the probe was of much help to the diagnostician.

The introduction of firearms made the use of entrance points more difficult to understand. The early types of firearms did not propel the missile with a very great velocity. Not infrequently, removal of a piece of shirt or other clothing from a wound brought the bullet out along with it. Later, as the velocity of the missile increased this seldom happened. However, usually the course of the bullet was very difficult to trace after it had entered the cavity. An exit point would sometimes simplify the diagnosis. Frequently how

Fig. 7. Charity Hospital of Louisiana at New Orleans in 1839. This structure was only relatively recently demolished to clear the ground for the present skyscraper building.

ever exit points are not present. Occasionally because of ricocheting when striking tissues of varying densities, the missile takes a more tortuous course than is expected, and when the peritoneal cavity is suspected of being almost certainly involved it is found not to be. On the other hand, when no involvement is suspected the danger signs of some serious injury to important structures frequently follow. In general, however, the presence of entrance and exit points gives a fairly accurate idea of the course of a bullet and the structures possibly injured.

As pointed out by Baudens, when a sponge on a holder is passed through a small opening into the abdomen, the finding of free blood, feces, or bubbling gas in the peritoneal cavity is unmistakable evidence of injury to a blood vessel or the intestines. However, evidence of this type is unusual, especially in abdominal penetrating wounds observed among civilians. Of great importance, too, but not infrequently misleading, are abdominal pain, nausea, and vomiting. This triad is very important, and usually points to visceral injury within the peritoneal cavity. A silent abdomen, on auscultation, is usually indicative of intestinal perforation. Pallor, a rapid pulse, thirst, and profuse perspiration point very strongly to possible active internal hemorrhage. Since the largest number of the patients die of hemorrhage (60) early diagnosis of this condition is most important. Every patient with abdominal trauma should be made to void or, if necessary, catheter-

ized for the possible presence of blood in the urine. If indicated, a digital and proctoscopic examination of the rectum should also be done.

An important method of diagnosis, introduced by Lenk during the first World War, was the use of the fluoroscope for air under the diaphragm. The use of the x-rays to locate a missile as pointed out by Granger is likewise of value, since the course of a missile might frequently be reconstructed when it is properly located in the body. The recent use of the peritoneoscope by Hamilton in gunshot and stab wounds of the abdomen of doubtful penetration" has added another diagnostic method that may prove to be of value in the future. The great importance of a correct pre-operative diagnosis in these cases was universally appreciated during the recently ended World War II. Michels is of the opinion that this helps to explain the "superior" results thus obtained among these cases.

NEW ORLEANS CHARITY HOSPITAL

After a careful study of penetrating gunshot and stab wounds of the abdomen in patients admitted to the Charity Hospital of Louisiana at New Orleans, the author agrees with Matas (72) that, aside from an actual seat of war, possibly no other hospital in the world sees and treats as many cases of penetrating abdominal injuries as does this great medical institution. From January 1, 1927 to January 1, 1948 this hospital has admitted 1,352 cases of penetrating abdominal gunshot

Fig 8 Charity Hospital of Louisiana at New Orleans as it appears today

and stab wounds, 685 of which were gunshot injuries. During this same time, 1,369 cases of penetrating gunshot and stab wounds of the chest were admitted, 968 of which were stab injuries. Thus over a period of 21 years this institution has admitted 2,721 cases of penetrating gunshot and stab wounds involving the chest, abdomen or both of these cavities.

This unenviable reputation quite naturally reflects the activities and tendencies of a section of the country in which a large proportion of the population are negroes. Accordingly among the 2,721 patients 2081 or 76.5 per cent, belonged to this race. Among the abdominal cases 69.2 per cent occurred in negroes. Hence the unusually large number of such cases seen at this institution is in great part due to the large negro population of this section.

The experiences at this hospital with these types of cases no doubt date back to its founding in 1837. Thus far however the first published record the writer has been able to find is a discussion by Richardson, Professor of Surgery in the Medical Department of the University of Louisiana (Tulane) at a symposium on abdominal gunshot wounds held by the American Surgical Association in May 1887. In his discussion, Richardson said that a large proportion of cases of penetrating wounds of the abdomen get well without laparotomy at the New Orleans Charity Hospital and further stated that during the previous 5 years (1882-1887) of the 31 patients admitted with knife wounds of the abdomen, 24 recovered, and of the 33 with

gunshot wounds involving this cavity 13 recovered. Additional studies and contributions on this subject from this institution were later made by Miles, to whom Matas (72) gives credit for inaugurating the operative treatment of these

Average monthly	63			
Average daily	2.1			

These figures do not include other types of violence as injuries with blunt weapons (beaters, iron bars, clubs) poisoning nor does this include venereal injuries.

Fig. 9. Sociologic aspects of penetrating abdominal gunshot wounds in recent series (478 cases admitted to the New Orleans Charity Hospital from January 1, 1927 to January 1, 1942. The apparent decline in admissions during 1939, 1940, and 1941 may be due to the increased number of men between the ages of 20 and 40 being drafted into the Armed Forces during these years.

wounds at the Charity Hospital, Parker and Fenner Shands, Allen, Crawford, with relatively recent contributions by Loria (58, 59, 60, 61, 63) Miller and Storck (101) the latter two reporting on their personal cases.

In this connection, the writer is pleased to express his sincere and very grateful appreciation of the opportunities and encouragement for the study of abdominal gunshot wounds that he has derived from his honored chief, teacher and friend, Professor Rudolph Matas. It was while serving as clinical assistant on Professor Matas' staff at the Charity Hospital—during the time the writer had the privilege and honor of serving his surgical apprenticeship under him—that he was impressed with the importance of further study in this field of traumatic surgery. In 1925 the Charity Hospital Surgical Staff appointed a committee for the study of gunshot wounds of the abdomen. Dr. Matas was named Chairman of this Committee. All cases of abdominal gunshot wounds admitted to the institution during the years 1925 and 1926 were observed and carefully studied by the writer and yearly reports were made by the Chairman to the Surgical Staff (66). It was the study of these cases and the statistical work done during this time under Professor Matas' direction that have served as a foundation for the writer's later contributions on this subject.

Dr. Matas, assisted by Mr. Edward Hynes (72) was the first, in 1901, to utilize the collective Charity Hospital statistics for comparative racial incidence and mortality of abdominal gunshot wounds in relation to the population, and in comparison with other general hospitals of the same type in the United States and Canada, taking the statistics of the hospital in the decennium from 1890 to 1900 for this purpose. They found that the general State hospitals of the same type in New York, Boston, Philadelphia, Cincinnati, St. Louis, and Montreal had admitted a total of 205 cases of gunshot wounds of the abdomen during the decennium considered, while the Charity Hospital had admitted and treated 234 cases during the same period. It is interesting to note that among the 122 patients operated upon in this Charity Hospital series, there were 84 fatalities, a mortality rate of 68.9 per cent, whereas, among the 112 nonoperative patients, there were 60 deaths, a mortality rate of 53.6 per cent (69).

Recent studies by the writer (61, 63) of all cases admitted to this institution from January 1, 1927 to 1948 have revealed an enviable wealth of material, the analysis of which is still far from being complete. From January 1, 1900 to January 1, 1948, a total of 1,678 patients with penetrating abdominal gunshot wounds have been admitted to this institution for treatment. By adding the

Fig. 10. Age incidence in the recently studied 478 cases of penetrating abdominal gunshot wounds at the New Orleans Charity Hospital. It will be seen that the greatest number of victims are between 30 and 40 years of age—nearly two-thirds.

234 patients admitted from 1890 to 1900 as reported by Matas (72) we find a total of 1,912 patients with penetrating abdominal gunshot wounds treated at the New Orleans Charity Hospital over a period of 58 years—an average of about 33 cases each year. Recent studies on penetrating stab wounds of the abdomen show that 1,439 patients were admitted to this institution from January 1, 1900 to January 1, 1948. Hence, over a period of 48 years 3,117 patients with penetrating gunshot and stab wounds of the abdomen have been admitted to this hospital for treatment an average of 65 each year or 1 nearly every 6 days. It is not surprising then, that La Garde (72) during World War I jokingly suggested that the students in the Army Medical School should come to the Charity Hospital for part of their military training.

THE LATE SPANISH CIVIL WAR

A brief review of the literature dealing with this type of injury during the late Spanish Civil War is of particular interest mainly because of the appalling and frightful mortality rates reported (64.8-96) by the surgeons on each side. Sevilla summarized the experiences on the six most important sectors or battle fronts in the campaigns of the army under General Francisco Franco. The

lowest mortality rate reported by him 53.7 per cent, occurred among patients treated on the Northern Front. The highest mortality 71.8 per cent, occurred in the Teruel Sector. Baron, too reported mortality rates between 53 and 75 per cent for this type of injury. The figures reported by Jolly for this type of wound are no more encouraging.

Especially interesting is Jolly's observation that the majority of cases can be classified into three clinical groups.⁷³ According to him these three groups depend upon the signs and symptoms which indicate predominantly (1) an appreciable blood loss by the victim, (2) evidence of perforation of the gastrointestinal tract, or (3) evidence in which the dominating injury appears to be to the sympathetic ganglia and plexuses in the upper retroperitoneal region.

In discussing the prognostic factors Jolly emphasizes (1) the time lag (2) the type of projectile, (3) the physical condition of the wounded man before the injury (4) the site and direction of the wound, (5) the organ or organs affected (6) the conditions under which the operation takes place, and (7) the possibilities for blood transfusion as useful guides. According to Trueta the Spanish Civil War contributed "one development which is now universally accepted

Fig. 1. Criminal status of the recently studied 478 cases of penetrating abdominal gunshot wounds at the New Orleans Charity Hospital. As noted the violence among these victims is predominantly homicidal.

TABLE II.—CAUSES OF DEATH AMONG THE 478 CASES OF PENETRATING ABDOMINAL GUNSHOT WOUNDS RECENTLY STUDIED AT THE NEW ORLEANS CHARITY HOSPITAL. THE ANALYSIS SHOWS THE CAUSES OF DEATH IN RELATIONSHIP TO THE TYPE OF HEMORRHAGE AMONG THESE FATAL CASES

Cases	Deaths	Hemorrhage		Undetermined
		Mediastinal	Massive

as part of the surgical treatment of war casualties, and that is the collection, proper storage and dispatch of blood donated by the civilian population for use in the combat areas. The Republican Army Medical Corps used "small medical units in the field" as transfusion teams, whereas in Franco's armies the transfusions were usually given at fully equipped medical centers in the rear. The newly introduced sulfonamides were first used in 1937 (194) in some cases of seriously infected war wounds. Jolly mentions nothing about the use of the sulfonamides in cases of abdominal wounds.

Jolly states that to-day there can be no excuse for conservative treatment of abdominal gunshot injuries. Surgical intervention is therefore advised in all cases except (1) the ones in which general peritonitis is well advanced, (2) those failing to show evidence of hollow viscus perforation and in which there is not enough blood loss to endanger life (3) moribund cases, and (4) those cases in which there are additional wounds that are obviously incompatible with life. He says further that a "blood transfusion should be started just before operation" in these cases. Either is considered the anesthetic of choice "when gas and oxygen are not available."

In his discussion of the operative treatment of this type of case Jolly emphasizes the importance of systematic exploration. He cautions that unless this is done "lesions will be missed." It is advised that if the lesion is predominantly hemorrhagic the bleeding point or points should be found as soon as possible, and "the liver, spleen, mesentery and posterior abdominal wall should be examined in that order." When the injury or injuries are predominantly perforations of the hol-

LORIA PENETRATING WOUNDS OF THE ABDOMEN

viscera each lesion should be marked with a table (Poirer) forceps and the search continued other lesions. After one is satisfied that no other injuries are present repair is done in a systematic fashion. By following this plan valuable time is saved.

Of interest in this connection is Jolly's recommendation that resection of the colon should be done in those cases of large bowel injury showing 'larger tears and retroperitoneal wounds' of the fixed portion of the colon. This should be done he says, 'notwithstanding the appalling mortality rate.'

The treatment of injuries to the rectum depends upon whether the wounds are extraperitoneal or intraperitoneal. The latter are the most serious and are usually attended by a higher mortality rate. The former are managed by primary removal of the coccyx and sometimes, too, of a portion of the sacrum. However it is further advised that if such an extensive operation is done for repair of injuries to the rectum it will be unsatisfactory unless a colostomy is performed at the same time.

Liver wounds, which varied in type and severity were treated according to the exigencies of the case. When it was believed certain that there was no injury to the hollow viscera they were treated conservatively. However if injury to a hollow viscus could not be excluded or if there was any doubt at all regarding this matter celiotomy was considered to be mandatory. Large liver lacerations were packed. Smaller fissure wounds were sutured with deep mattress sutures of catgut, a fringe of the omentum being introduced into the lips of the crater before tying.

Unless wounds of the spleen were very trivial and not bleeding removal was considered the procedure of choice. Jolly is of the opinion that wounds of the pancreas are 'nearly always fatal. It is his further opinion that these lesions are seldom seen or seldom found. Except for drainage used in cases of injury to the pancreas, drainage of the abdominal cavity should be abandoned for gunshot wounds of the abdomen.

In the discussion of the postoperative care of cases of abdominal gunshot injuries Jolly emphasized the importance of morphine the giving of small quantities of fluids by mouth and the establishment and maintenance of a proper fluid balance. In this regard it is his feeling that had it been possible to use the 'Abbot jejunoileal tube for decompression of these cases during the Spanish Civil War more lives might have been saved. Although Jolly gives an incidence of 11 per cent in abdominothoracic wounds his series does not

Fig. 13. Diagrammatic sketch showing the relationship of adjacent abdominothoracic structures, and why penetrating wounds of the abdomen or chest at proper levels frequently involve both cavities.

include casualties in which bullet wounds obviously affected the abdominal cavity but in which because only the liver was affected and hemorrhage did not threaten life, operation was not called for. Inclusion of these cases would have undoubtedly increased the incidence of this special type of case. The management of this type of wound introduced special problems and the choice of abdominal thoracic or combined abdominothoracic approach for the operation in these cases depended upon the special problems presented.

EXPERIENCES DURING WORLD WAR II

The usual general interest in the surgery of abdominal trauma is always considerably intensified during wartime. Hence the appearance in the literature of more than 359 articles on abdominal gunshot injuries—only one of the many types of injuries involving this cavity—from January 1940 to June 1946 inclusive is not by any means unexpected. Although some of these contributions have come from civilian sources an increasing number represents the studies, personal experiences and observations of a large number of surgeons serving in the Armed Forces during the recent second World War.

The various phases and aspects of the abdominal injuries of warfare including their complications, were rather thoroughly considered at the start of the second World War by (1) the Committee on Surgery of the Division of Medical

Sciences of the National Research Council, whose contribution on Abdominal Injuries was prepared by Storck (102) by (2) Davis, Heyd, Gordon Taylor (38), and Fulton, and by (3) Fraser (33) (34) (35) Charles Gordon-Taylor (39) Gordon Watson and Morgan, and McFadden and Galloway. The first of these contributions represents the official manual of the United States Armed Forces on the management of abdominal wounds. The second group, nearly all by Americans, comprises outstanding authorities on the subjects discussed, whose individual contributions are grouped in one volume entitled "War Medicine." The third is by a group of British authorities whose respective contributions appear in the "Surgery of Modern Warfare" edited by Hamilton Bailey. As the War progressed these contributions were supplemented by bulletins on abdominal injuries issued by the War Offices of America and Britain from time to time. Because of its interesting aspects, one such bulletin is quoted in full at the end of this section.

Most writers on this subject have a distinct appreciation of the lethal character of abdominal gunshot wounds. However the frightful realities of penetrating abdominal wounds, especially as they apply to modern total warfare, have never been sufficiently emphasized to make us appreciate the true and full significance of this type of injury. Goetze (1939) is quoted by Baron as saying that theoretically we may say that under optimum conditions of surgical technique and transportation in warfare, it is possible to save from 25 to 30 per cent of the patients with penetrating wounds of the abdomen who would be doomed to certain death without operation. In his analysis of this problem, Baron continues by saying that

when we face the cruel realities of World War I, as they apply to our (Spanish) experiences, we see that while it is true that from 1,850 to 3,700 abdominally stricken soldiers owe their lives to timely surgery by celiotomy we also realize the relative insignificance of our contribution when we find that the deaths of 10 per cent of the 1,185,000 soldiers killed outright on the battle fields of World War I were caused by the shock and hemorrhage of penetrating abdominal wounds! On the strength of this statement, therefore, 118,500 soldiers, victims of penetrating abdominal gunshot wounds on the fields of battle during the first World War died before any surgical help could possibly reach them. This is indeed a very gloomy and challenging revelation. However the encouraging reports that have come in from the recent (second) World War make it appear that the improved transportation facilities

and the improved methods of management generally have cut the mortality figures down rather appreciably.

Most observers during the recent World War II seem to agree that the splendid improvement in the mortality rate (23 47 93 80 100) of abdominal gunshot injuries is largely explained by three factors: (1) the free availability of large quantities of plasma and blood for resuscitation and the treatment of shock (10, 25, 47 93) (2) the judicious use of chemotherapeutic agents—the sulfa drugs at first and later the antibiotic penicillin (4 46, 65) and (3) improved surgical methods and techniques. To these one should undoubtedly add the improved facilities for the preoperative and postoperative treatment in these cases, many of which were already in civilian use before the War. Hence the improved method of gastrointestinal drainage, the availability of the Miller Abbott tube, a better understanding of the importance of a proper fluid and electrolyte balance, and other advances and improvements in the management of the surgical patient, practically none of which were available to the surgeon in the first World War undoubtedly had much to do with the great decrease in the mortality rate among the abdominally injured in World War II. In addition, the presence of many well trained and qualified anesthetists to supervise the administration of anesthetics to these patients at all hospitals, unquestionably also had much to do with the increased recovery rates reported (23 47 80 85, 93, 100).

Another factor of great importance in cutting down the mortality rate from the previous usually high figures was the great care taken by the surgeon in attempting to establish a more precise preoperative diagnosis in these cases (75). At no time in the past has this type of injury been so diligently and thoroughly studied as during the recently ended conflict. Every conceivable factor and possibility were given the greatest consideration in an effort to reduce the mortality rate among the victims of abdominal injuries. As a result, such problems as abdominothoracic gunshot injuries, air blast injuries, water blast injuries, and injuries to the extraperitoneal structures—especially the kidneys and extraperitoneal portion of the rectum—were understood better and treated with more success than at any previous time.

Because two very important cavities are involved in abdominothoracic gunshot wounds, there is always doubt as regards the seriousness of the abdominal or thoracic injuries. Even after careful study and consideration the surgeon is often in doubt as to whether he should open the chest,

the abdomen, or both. The special difficulties usually encountered in this kind of injury are well discussed by Gordon-Taylor and others (38, 48, 61). Studies by these writers give the impression that the mortality rate among such cases is greater than among the cases in which the abdomen alone is involved. In general the mortality rate among victims of abdominothoracic gunshot wounds depends upon the organs or structures damaged, the extent of the injuries, and the condition of the victim when injured.

BLAST INJURIES

During the first World War one of the most frequently observed disturbances, occurring especially in areas of artillery action, became known as shell shock or shell concussion. The victims of such injuries were often found unconscious, or at times in a semiconscious condition, and yet showed no evidence of any actual external injury. Not infrequently the victims of such injuries were found dead. Autopsies showed evidence of numerous petechial hemorrhages in the brain. In addition Mott also showed that many of these patients were actually the victims of carbon monoxide poisoning and it was further shown (36) that many of the deaths from blast really resulted from carbon monoxide poisoning of victims who were rendered unconscious and who were trapped under fallen debris. It is now believed by some that many of the "shell shock" and "shell concussion" cases of the first World War were possibly cases of what we now know as blast injuries.

In the War just ended blast injuries attracted considerable attention and were the subject of many studies and reports (7, 39, 110, 111) made especially by the British. As one surveys the literature on this type of injury he is impressed with the fact that air blast victims suffer injuries predominantly to the structures within the thoracic cavity especially the lungs (5). On the other hand, "underwater" or "immersion blast" injuries result in damage affecting principally the intraperitoneal structures. Solid blast injuries (7) usually result in fractures involving the lower extremities, the hips, pelvis, or spine. Thus far the writer has been unable to locate any reference to solid blast injuries which caused damage to intra-abdominal or intrathoracic structures. On the other hand air blast injuries although predominantly involving the intrathoracic structures, may likewise be complicated by some intra-abdominal damage, and "immersion blast" injuries, although mainly involving the intra-abdominal structures, may also result in trauma to the lungs. It is very likely, too, that all types of blast injury

Fig. 14. Graph showing relationship of hemorrhage to mortality rate in a comparative study of 100 cases admitted to the New Orleans Charity Hospital from July 9, 1938 to July 9, 1943. The influence of chemotherapy on 49 patients is compared with a group of 51 cases receiving no chemotherapy during this same period of time.

victims also have an involvement of the central nervous system to a lesser or greater extent.

It is the opinion of Rose and Watson (94) that the prognosis of an abdominal injury whether subcutaneous or penetrating is rendered graver when the injury is accompanied or complicated by blast effects. The pathologic findings in blast injuries which predominantly involve the chest are pulmonary hemorrhages of varying degrees, contusions, and possible lacerations of other intrathoracic structures. Blast injuries which predominantly involve the abdomen result in submucosal, subserous, or intramuscular hemorrhagic areas that may be found in any part of the gastrointestinal tract but more especially the lower ileum and large bowel. Such hematomas may also be seen in the great omentum and mesentery as well as in the retroperitoneal tissues and the solid viscera. When perforations or lacerations occur, they are more likely to involve the small intestine. Hence, although death from uncomplicated primary blast was rather rare, some of these patients were injured sufficiently seriously to succumb.

The signs and symptoms of blast injuries of the abdomen are essentially those seen in any acute abdominal catastrophe. Severe abdominal pain is frequently accompanied by nausea and vomiting. There is usually generalized rigidity and tenderness. An absence of peristaltic waves should make one very suspicious of intestinal perforation. This may be confirmed by the finding of free air in the peritoneal cavity on x-ray examination. Unless there was very serious damage such as intestinal perforation or laceration of a solid viscus, almost all of these cases showed evidence of improvement after several hours, following which the signs of serious or grave danger disappeared more rapidly.

All patients with blast injuries were treated with the usual resuscitative measures. Plasma and blood were given freely. Every effort was made to restore the victim's normal fluid and electrolyte balance. It was indeed seldom that any patient with a blast injury involving the chest required operation. Some of those with abdominal blast injuries, especially those showing evidence of intestinal perforation or severe internal hemorrhage, had to be celiotomized, and, frequently the victim's life was saved.

INJURIES TO THE EXTRAPERITONEAL STRUCTURES

In general, the question of preoperative diagnosis in abdominal injuries, and especially those involving the extraperitoneal portion of the rectum and other extraperitoneal structures, has previously been given too little attention. Mainly because of this lackadaisical attitude usually on the part of those handling these cases, many victims of traumatic abdominal catastrophes who might have been saved have died. The mortality rates in the past have been extremely high. Not infrequently the surgeon, because he believed the missile could not have passed through a given area, or because he felt that a given crush injury could not have involved a given structure, has failed to repair damage that ultimately meant death to the victim. Failure to examine the urine preoperatively or to examine the rectum digitally or proctoscopically has on occasions caused the attending surgeon much embarrassment postoperatively.

The lessons learned in the past along these lines were very useful in the recently ended second World War and, undoubtedly, led to the saving of many additional lives. The percentage of overlooked serious injuries to abdominal structures was probably less during the recently ended conflict than heretofore. Badly damaged kidneys were removed and the loss of blood from this source stopped in time to save the life of many such vic-

tims. Catheterization often revealed injury to the kidney, ureter bladder or urethra which might otherwise have been overlooked. Digital and proctoscopic examinations of the rectum often surprised the examiner with evidence of injury to this structure. Hence, the greater care exercised in making a more accurate preoperative diagnosis in these cases of injury to the extraperitoneal portion of the rectum and other extraperitoneal structures, undoubtedly had much to do with the lowered mortality rates reported by many writers (18, 20, 41, 54, 55). The adage to be forewarned is to be forearmed is just as important to the surgeon in dealing with abdominal catastrophes as it is to anyone else in any other field.

Injuries involving the abdomen—especially the lower half—the buttocks, sacrum, or hips, or any gunshot injuries of the posterior aspect of the thigh which seem to have an upward course, particularly when there is no exit point, should invariably call for at least a digital examination of the rectum. If considered necessary a proctoscopic examination very carefully done, should also be made. According to Laufman, the patient with a penetration of the extraperitoneal portion of the rectum may present no symptoms referable to this organ at the time of initial examination. Although only 6 per cent (55) of all buttock wounds involve the rectum it is well to keep Laufman's warning in mind that "missiles entering the body anywhere between the levels of the lower thigh and the costal margin have been known to penetrate the rectum."

The operative treatment of wounds involving the extraperitoneal portion of the rectum is divided into two phases: (1) the management of the rectal injury and (2) the construction of a temporary occlusive colostomy. "It is considered best to do the perineal or posterior portion of the operation first. Adequate drainage of the perirectal region is of great importance. Laufman believes that it is not necessary to remove the coccyx to secure good drainage of the perirectal space. In addition to proper and adequate drainage of the perirectal space, a thorough debridement of the area involved should always be done, and any large defect in the rectal wall should be properly repaired.

UNUSUAL INJURIES INVOLVING THE PERITONEAL CAVITY

The most unusual kinds of accidents have been known to result in injuries involving the peritoneal cavity as well as other cavities. Among the most interesting of these are impalements and other accidents of a similar nature.

Although impalement is not considered as a diagnosis in the last (1946) edition of the 'Standard Nomenclature of Disease and Standard Nomenclature of Operations' published by the American Medical Association, this unusual and frequently bizarre, ghastly, and gruesome condition is so different from the usually pictured penetrating and perforating wound of the pentoneal cavity that it appears more proper to discuss it under this heading. Certainly such accidents give rise to unusual and very often freakish injuries involving the body cavities. Historically no other type of wound is as interesting as impaling injuries.

According to Pennington, the Oriental races have always been noted for their ability to devise fiendish forms of punishment, and one of their devices was impalement. This was carried out in two ways—the victim was laid down and the stake driven into the body or else it was planted in the earth and the culprit fastened to it so his weight caused the body to become impaled. This form of punishment dates back to the hoary past.

"In ancient Rome impalement was at first restricted to slaves who had been guilty of robbery. Later on Nero resorted to it among other measures in his persecutions of the Christians. Soon after the irruption of the Ottoman Turks into Europe they made use of it for various offenses. Those guilty of business transactions between Mohammedans and Christians, treason, fraud against the Sultan, etc. In Russia Germany and Austria, it was generally prevalent up to a comparatively recent period in cases of murder and witchcraft. For adulterers caught *in flagranti delicto* according to Silberman double impalement was in vogue. We learn from Fairlie, that in the Malay Peninsula, a unique method is in use for female marital infidelity. Some species of bamboo grow there with extraordinary rapidity and the one selected increases in length 24 inches in 24 hours. A young shoot just sprouting from the ground is selected, and the end whittled to a sharp point the condemned woman being lashed to stakes over the bamboo is impaled in two days.

During the hand-to-hand combats of the Middle Ages, when the body was largely protected by plate-and-mail armor, the rectum probably escaped injury. Though this immunity disappeared with the introduction of gunpowder. However, the feeble penetrating power of the old round—and even the conical bullet later had little effect on the lower bowel in its bony encasement. With the advent of the modern small bore projectile of enormous velocity which respects nothing in its course, rectal wounds, have become relatively numerous.

'One of the English kings, Edward II, was murdered (A.D. 1327) by having a red hot iron thrust up the rectum and it is rumored this was one of the many arguments adopted by the Inquisition to admonish heretics. At the time (17th and 18th centuries) when clysters were a panacea for every imaginable ill, and they were administered by the ignorant nurses of the day or even laymen, e.g. druggists, apprentices, serious and fatal injuries from the syringe points were somewhat frequent. This was before the days of rubber when metallic instruments alone were available in fact, such mishaps have been recorded well into the last century.

Today although impaling wounds are relatively rare, they nevertheless rather frequently involve the pentoneal cavity and are of sufficient importance to be included in any discussion which considers trauma to the perineum in general and to the vagina, anus, and rectum in particular. It is of interest to note, according to Black (11) that seven cases of rectal impalement with damage to intrapentoneal viscera were encountered at the (Mayo) Clinic from 1910 to January 1 1939. From January 1 1896 to January 1 1948 the Charity Hospital of Louisiana at New Orleans admitted 12 cases of impalement wounds which involved the abdomen. Five of the patients were negro males. Among the 7 white patients 2 were females.

Almost every perineal and pelvic structure, and many abdominal and thoracic structures have been injured (66-87) as a result of impalement. Although the literature on this subject is small interesting individual cases, as well as collected groups of such cases, have been reported from time to time. Impalement injuries are very rare in warfare. They are almost entirely a civilian type of injury relatively more commonly seen in agricultural districts. Severe and serious injuries to the urethra, vagina, urinary bladder, prostate gland, seminal vesicles, and ureters are not infrequent, and injury to almost any portion of the gastrointestinal tract is not impossible. Usually because of the manner of entrance of the impaling object, as well as the position of the large vessels, injury to the latter is relatively rare. Most of the fatalities in this kind of case result from generalized peritonitis. Relatively few victims die of hemorrhage and shock.

Most impaled injuries result from falling in such a way that the body strikes the object usually a stake or picket, with a considerable force. Possibly no other field in traumatic surgery can claim any more unusual and bizarre kinds of accidents than this one. In many instances, perversions have been responsible for the introduction

of rather large, gruesome, and ghastly foreign bodies into the vagina and rectum. The introduction of rather stiff rectal rubber tubes have been known to result in perforations of the recto-sigmoid. Proctoscopic examinations (95) and enemas (81) have also resulted in serious injury to the bowel.

Involvement of the peritoneal cavity is often very difficult to determine. Frequently, the victim removes the foreign body and walks a long distance to his home. However the onset of severe lower abdominal pain followed often by collapse should remove all doubt as regards the advisability of emergency celiotomy. Digital examination of the rectum, although indicated, will frequently give very little information. Proctoscopic examination is usually mandatory and the finding of air under the diaphragm is practically positive evidence of intestinal perforation. Bloody urine is almost invariably conclusive proof of serious injury to the urethra, bladder or ureters. Nausea, vomiting, a rapid pulse, and fever are signs which develop somewhat later. In the transportation of these patients, the sitting or semi sitting position is considered best and advisable.

Synopsis of 4 of the 12 cases of impalement received at the New Orleans Charity Hospital are being given because of their unusual and interesting aspects.

CASE 2. A white male, a fireman 34 years of age, who on December 5, 1933 was struck in the buttocks and in the perineum by a forceful stream of water from a fire hose. Upon admission to the hospital, his scrotum was found to be markedly swollen and painful. A 6 inch laceration exposed the muscles on the inner aspect of his right thigh. The perineum was lacerated in a stellate manner and the sphincter was torn in its posterior area. The laceration ran up the posterior aspect of the rectum for 3 or 4 inches. Treatment consisted of packing and daily irrigations. The patient left the hospital on March 23, 1934.

CASE 3. A white male saw-miller, a laborer of 56 years. While at his work on December 9, 1934, stick flew off of the saw and entered the lower left abdominal quadrant making its exit in the right gluteal region. At operation, the stick was found to have struck the iliac crest in such a way that it split and one portion passed through the gluteal muscles to the right. The other portion, nearly 1 inch in diameter and 3 inches long, directed the left iliopectineus muscle as high as the kidney. Multiple lacerations were found in the ileum and feet had to be resected. Other pieces of splinter were removed. The patient died of generalized peritonitis on December 27, 1934.

CASE 4. A male negro, 6 years of age, who was admitted on April 21, 1939. While riding a horse, the patient fell off and landed on a picket which penetrated the right side of his abdomen. In the operating room, pieces of clothing were removed from the abdominal wound. When the abdomen was opened, piece of wood 12 inches long, 3/4 inches wide, and 1/2 inch thick was found to be wrapped up with omentum. A 3/4 inch transverse rent in the descending colon was repaired. The stick was freed from the omentum with difficulty and was only "pulled" from the

wound "after a mighty heave." The patient expired the next day.

CASE 4. A white female, 28 years of age. She was admitted to the hospital on January 19, 1943 with the complaint of "bottle in rectum." The patient said that a friend introduced a coca cola bottle in her rectum while she was intoxicated. Examination showed the base of coca cola bottle 3 1/2 inches above the rectal sphincter.

Under spinal anesthesia, the bottle was extracted with large clamp with some difficulty. No perforation was observed. Twelve hours later the patient presented evidence of generalized peritonitis. An emergency operation was performed and generalized peritonitis, more pronounced in the pelvis, was found. No attempt to find the site of perforation was made. About 900 c.c. of purulent material were aspirated from the pelvis. Mikkilix colostomy of the sigmoid was done, and the patient returned to the ward in fair condition. She left the hospital on February 24, 1943 and on September 18, 1943 the colostomy was closed.

Of unusual interest, also, are 2 cases of such injuries treated by two colleagues, Drs. H. H. Russell and D. J. Murphy at the Hotel Dieu Hospital of New Orleans.

CASE 5. A white female, 57 years of age was first seen on August 23, 1943 with the complaint of severe lower abdominal pain, fever, nausea, and vomiting. The history revealed that 3 or 4 days previously a rectal examination was done elsewhere with a proctoscope. On August 24 a vaginal diagnostic aspiration of the cul-de-sac showed the presence of a foul smelling fluid with a Bacillus coli odor. On September 4, 1943, posterior colpotomy allowed the escape of about 600 c.c. of foul smelling sanguinopurulent material. The patient was discharged from the hospital on September 9, 1943 after a very stormy postoperative state.

CASE 6. A white male, 48 years of age, was admitted on January 3, 1946 with the complaint of severe abdominal pain. A few hours before, this patient, because he had been constipated, took an enema by attaching the rubber tubing of an enema bag to the faucet of his bath tub. He inserted the nozzle into his rectum and turned on the water. After "a brief period," he was seized with sudden violent abdominal pain and collapsed on the floor. Upon reaching the hospital in an ambulance he was more comfortable and refused operation. However on January 8 days after admission, he consented to an operation. This was done under spinal anesthesia and large amount of fluid feces was found in the peritoneal cavity and removed. In the terminal ileum, there was found rent about 2 1/2 inches long. About 3 feet of ileum were resected. The patient died about 4 hours later.

Autopsy showed, among the usual other findings, "traumatic rupture of the rectum and ileum" and generalized peritonitis.

ANESTHESIA IN THE SURGERY OF ABDOMINAL TRAUMA

It is doubtful that any sufficiently effective anesthetic agent was ever used in the management of abdominal injuries before 1846. It is very likely too that patients with abdominal trauma were among those subjected to operation, under the influence of ether or chloroform, during the period of greatest controversy regarding anesthesia in this country between 1846 and 1863. Spinal an-

esthesia introduced in 1885 by Corning (56) was probably not used in the operative treatment of these patients until after the beginning of the present century.

The story of the development of anesthesia so interestingly told by Keys and so excellently and thoroughly outlined by Lenke plays a most important role in the management of all types of wounds of the abdomen and chest. To the surgeon who has been given the responsibility of treating a seriously wounded abdomen there is nothing as important during the period of operation as a well relaxed and calm abdomen. It is only an abdomen in this condition that will permit of the most thorough exploration with the least added trauma and in the shortest period of time. Nothing will handicap the surgeon's work in these cases more than a poorly administered anesthetic and nothing will help the causes of thoroughness and expeditiousness more than a good relaxing anesthetic.

Plain drop ether was for many years the anesthetic of choice in the operative treatment of the injured abdomen especially at the New Orleans Charity Hospital. Gillies and Evans say that in surgery for abdominal trauma, inhalational anesthesia with nitrous oxide and oxygen, supplemented by local infiltration or intercostal nerve block is the method of choice, especially in the presence of shock. Alternatively cyclopropane and oxygen may be used, and in cases exhibiting little or no shock gas, oxygen and ether may be required because the threshold of the patient's resistance to anesthesia has remained at its normal level. Turnbow is of the opinion that "in general combinations of anesthetic agents are safer for seriously injured patients." He considers spinal anesthesia to be unsafe and was used infrequently. To the majority of his cases, Eatoo induced anesthesia with ethyl chloride or pentothal then switching over to warm ether from the Oxford vaporizer. In general, most of the surgeons reporting their experiences during the recent World War (II) preferred ether as the anesthetic of choice. Induction was usually accomplished with nitrous oxide or pentothal sodium given intravenously.

Almost from the time it was introduced spinal anesthesia has been considered very dangerous in this type of patient, and the chief reason given is that it adds to the shock of these usually already shocked patients whose general preoperative condition is frequently very poor. Nearly all reports from the recently ended War condemn spinal anesthesia as being unsafe and dangerous in these

TABLE III—TYPES OF ANESTHESIA USED IN 366 CASES OF PENETRATING ABDOMINAL GUNSHOT WOUNDS OPERATED UPON AT THE NEW ORLEANS CHARITY HOSPITAL BETWEEN JANUARY 1 1927 AND JANUARY 1 1942 IT IS INTERESTING TO NOTE THAT THE GROUP OPERATED UPON UNDER SPINAL ANESTHESIA SHOWED THE LOWEST MORTALITY RATE AMONG THE THREE LARGE GROUPS

Anesthesia	Total	Lived	Died	Mortality Per Cent
Ether				
Ethylene	10	83	108	56.54
Nitrous oxide and ether	7	8	3	23.33
Cyclopropane	3	4	3	71.43
Local	7	3	4	57.14
Spinal	74	51	23	31.08
Ether and ethylene	35	13	8	62.85
Spinal and ether	3		3	100.00
Epidural	5	0	5	100.00
Epidural, ether and ethylene			2	100.00
Epidural and ethylene		0		00.00
Cyclopropane and ether	10	13	3	18.75
General	4	3	2	50.00
Cyclopropane, the and ethylene		0	2	100.00
Ethylene and cyclopropane	2	2		0.00
Not given	4		8	100.00

cases. However none of these reports include any appreciable number of cases in which spinal anesthesia was used. On the other hand Davis has found spinal anesthesia the most suitable not withstanding the presence of severe shock and hemorrhage. In a relatively recent study of 478 cases of penetrating gunshot wounds of the abdomen the writer (62) found that a group of 74 patients operated upon under spinal anesthesia showed the lowest mortality among the large groups. The present general impression is, also that intravenous anesthesia is not especially suitable for cases of abdominal trauma unless oxygen and curare are used with it.

WAR BULLETIN ON ABDOMINAL WOUNDS

Of special interest during the recently ended World War were the bulletins on the management of different types of wounds issued by the various War Offices. One such bulletin, which reviews the general management of abdominal wounds in the light of relatively recent war experiences, and

which was issued by the British War Office, has been considered sufficiently interesting and important to be quoted in full in this presentation.

This article (4) should be regarded as an extension to chapter 20 of the Field Surgery Pocket Book. (1) What was written there in 1943 has stood up well to later experience in the field, but fresh campaigns have taught new lessons and re-emphasised the importance of old teachings—above all on the importance of postoperative care.

"When to operate"

Everyone agrees that men with abdominal wounds need operation as early as possible if they are to have the best chance. But too literal an interpretation of this phrase as early as possible may result in men being operated on in areas so far forward that bad conditions more than counter-balance the benefits of a few hours gained. It cannot be emphasised too strongly that men with belly wounds do badly in noisy surroundings; peace of mind is one of their great needs, and sick men cannot always differentiate the noise of our own guns from that of enemy bombs and shells. Sometimes in isolated places there was no alternative to operation on the spot—as on the Anzio beach-head—but the patients were in a constant state of alarm and never got really restful sleep. Some even jumped out of bed and crawled under it for protection, and many Field Medical Cards noted that the medical services were forced to evacuate this man because of his mental state. Under such unfavourable circumstances, heroic doses of luminal are justified. Grains 5 may be given twice daily and continued with safety for several days; this treatment does not paralyse bowel action, which is a serious objection to repeated doses of morphine.

In practice there are very few belly cases that cannot be sent off at once or after an hour's resuscitation. With a travelling transfusion (2) (in ambulance drip) where necessary they will travel safely and with great subsequent advantage, to a surgical centre some two hours down the road, where quiet and the best nursing can be given. It is of particular importance to the success of a travelling transfusion that the needle should be inserted far enough into the vein otherwise plasma leaks into the subcutaneous tissue. Apart from any other consequences, this completely spoils the area for further transfusion. Almost the only type of abdominal wound in which half-an-hour makes all the difference between life and death is that where haemorrhage is the predominant feature. These cases can be diagnosed by the presence of ab-

dominal rigidity, pallor, rapid pulse, and low blood pressure—signs that are established in about 2-3 hours after wounding. Therefore, unless the position is an isolated one or there is evidence of haemorrhage, all men with belly wounds should be sent to an Advanced Surgical Centre to have treatment in its safety and relative quiet.

Diagnosis

Position when wounded. It is important to try to learn from the patient what position he was in when he was wounded—was he standing, running, kneeling, crawling, prone, or what? The answer is of great help in working out the lesions that are to be expected.

Peristaltic sounds. The presence or absence of peristaltic sounds has considerable significance, though there is no absolute rule. When sounds are present there is not likely to be any perforation of a hollow viscus, though intestinal rumblings may be heard when there is a small hole in the pelvic or sigmoid colon. Absence of sounds is very suggestive of perforation of hollow viscera, but auscultation should be repeated at intervals, especially if there is no rigidity and if other signs—such as those of haemorrhage—are absent. A blow in the stomach or exposure to blast, may cause peristalsis to cease for an hour or so, after which it starts again.

Resuscitation

"As with all wounded, the sooner the man with wounds of the belly is got to an Advanced Surgical Centre the better, and it is important to persuade R.M.O.s. and M.O.s. of Field Ambulances not to spend too much time on resuscitation. (3) Not all abdominal cases require intravenous fluids, and when these are thought necessary it is best to give plasma unless there are signs of haemorrhage. Too much blood may precipitate anaemia in abdominal cases. At R.A.P. or A.D.S. level, it is better to give one or two pints only and then send the man without further delay to the Surgical Centre with a travelling transfusion in the ambulance. If signs of intra-abdominal haemorrhage are present, blood should be given in the same way, but in these circumstances it is even more important to get the patient to the surgeon as soon as possible.

Operation

"General. There is much to be said in favour of the midline incision. If a paramedian skin incision is used, the whole rectus muscle should be reflected laterally because the more usual practice of splitting the rectus may deprive the inner part of the muscle of its blood and nerve supply. Un-

hurred speed is essential for with every five minutes beyond the hour there is a worsening of the patient's condition. It is important to make the incision long enough, and to avoid pulhog on the parietes with retractors this always leads to a fall of blood pressure.

Anaesthetic. A number of surgeons and anaesthetists are now using intercostal block anaesthesia combined with light intratracheal gas, oxygen, and ether. All agree that this gives perfect relaxation and that post-operative chest complications are less common than with other anaesthetics.

'Colostomy' Every endeavour should be made to fashion a double-barrelled spur. When stitching the parallel limbs together it is a good thing to rotate the loop in its long axis somewhat, so that the contiguous surfaces are well away from the mesenteric border this obviates the risk of damage to the blood supply by the subsequent application of the enterotome.

'Large Intestine Wounds' Many experienced surgeons are moving away from the principle that a damaged colon must always be exteriorised. They feel that in the right half of the colon small perforations with clean-cut margins and no surrounding bruising can be safely dealt with by careful suture. A number of small perforations of the anterior wall of the rectum have been similarly treated. It is essential for safety however that a small drainage tube should be put down to the site of suture and left in position for three to four days and it is wise to cover the suture line with omentum if this is practicable. A variation is to anchor the sutured colon to the parietal peritoneum with a few stitches.

'Opinion has shifted thus from the more orthodox view because many surgeons felt that the amount of mobilisation which was sometimes necessary carried with it a risk of shock that was a greater danger to the patient than the possibility of an intra-abdominal abscess. They also knew from hard experience that colostomies performed hurriedly in a patient ill from multiple wounds are not always easy to close at a later date and of course, a colostomy is not a pleasant thing for the patient.

The results have been satisfactory to the hands of surgeons who have long experience and are skilled in their selection of cases the less mature who are in any doubt should always exteriorise it is worth repeating."

(1) suture should be employed only if the hole is small and there is no surrounding bruising of the adjacent bowel wall (2) a drainage tube should be employed.

Postoperative care

The first 24 hours after operation should be regarded as a second phase of shock initiated by a second trauma—the operation—and the same careful observations on blood pressure should be made as in the resuscitation ward. All cases return from the theatre on intravenous fluids serial blood pressure readings should help to fix the decision on the continued use of blood, plasma or glucose-saline and on the rate of the drip.

Gastric suction. Every belly case is put on continuous gastric suction this and intravenous therapy are usually maintained for about three days, until there is no distention and until peristalsis is active. From the second day onwards it is wise to give fluids by mouth clipping the suction tube for about an hour afterwards. These drinks can be started at the rate of 1 ounce 2 hourly for 12 hours then they can be increased to 2 and later to 3 ounces. It has been found in many cases that about one third of the fluid taken by mouth passes the pylorus and is absorbed. This in itself is valuable and has a great effect on the morale of the patient. It is a good thing also to include in these drinks nutrients such as glucose tinned milk, Benger's food, thin soups, and ice-cream. Aminoacids in their present preparations are too unpalatable for administration in this way but if this difficulty is overcome they will be of great value.

In the early days after operation it is most important to keep careful fluid charts that show intake by vein and mouth and output by urine and suction. Daily intake should be 4.5 pints in cool climates and 7-8 pints in hot weather.

To help overcome the lack of protein in this regime, one or two bottles of plasma (or serum which contains about twice as much protein as plasma) should be given daily. The Shock Research Team (3) has recently drawn attention to the serious deficiency in chlorides that develops early during this regime. On this point, the following remarks kindly offered by Dr R. A. McCooce are helpful. A rough way of meeting the salt requirements of the body is to give a pint of every pint of normal saline daily, plus one pint for every pint of gastric contents withdrawn by suction, but more saline (up to 4 pints) may be needed in tropical climates or if the urine does not contain chlorides. The remainder of the fluids given should be 5 per cent glucose or other non-saline fluids. About the 7th-8th day after operation, blood should be given if necessary to keep the haemoglobin level up to 60-70 per cent at the very least.

In quiet times each surgeon will probably wish to apply his own particular ideas about post-operative treatment, but when things are busy individual differences of detail must go overboard in favour of a common routine for all in the particular centre. It is best if a senior M.O. familiar with this type of work, can be put in charge of the post-operative ward, so that he can modify the routine according to the needs of individual patients.

"Complications"

"Anuria. Renal failure with anuria occurs in a proportion of all seriously wounded men, no matter whether they have been transfused with blood or with plasma or have not been transfused at all the incidence is relatively high with belly cases. The cause is not fully understood, but there can be little doubt that prolonged times anuria preceding restoration of circulatory efficiency may cause irreversible kidney damage, even though the patient's life is temporarily saved by resuscitation and operation. In belly cases additional factors may operate. Thus, there may be prolonged spasm of the renal arteries from irritation of the sympathetic ganglia by retroperitoneal haemorrhage around the coeliac plexus. Sympathetic overaction from the same cause may also explain the slowing down or cessation of intestinal peristalsis, with resulting distention: this is sometimes seen in oliguric cases, and is often associated with the retroperitoneal haemorrhage of fractures of the spine.

"A badly judged resuscitation technique may readily contribute to or even precipitate renal failure. Mis-matched transfusion, with gross intravascular haemolysis, is an obvious cause. Massive transfusions of old stored blood may likewise lead to a degree of intravascular haemolysis, which is the equivalent of a mis-matched transfusion. The Shock Research Team (3) have made surgeons alive to this risk.

Another factor which may lead to renal failure is the continuous administration of those sulpho-namides, which tend to form acetylated insoluble crystals (sulphapyridine, sulphathiazole, sulphadiazine) without careful supervision of fluid intake and urinary output.

"The most rational prophylactic treatment is to restore the efficiency of the circulation at the earliest possible moment, with plasma unless fresh blood is available. With an efficient circulation, blood is only required in an amount sufficient to ensure a haemoglobin level of not less than 70 per cent at operation. The second measure is to ensure adequate hydration with a good urinary output.

"When oliguria arises and anuria threatens, treatment is not promising, but it is worth trying some of the following:

(1) Sodium citrate, grains 120 at once and grains 60 every 4 hours.

(2) 600 c.c. sodium citrate (3%) in 500 c.c. glucose (5%) as a slow drip in 24 hours.

(3) 100 c.c. of 10-50 per cent glucose given slowly by the intravenous route. (The rationale of this suggestion rests on the idea of dehydrating an oedematous organ by hypertonic solutions. For diuresis, 10-20 per cent solutions of glucose are generally used, but 50 per cent solutions can be given without ill effect.)

"Conservative Treatment"

It may be possible for the surgeon to treat a case expectantly if with the help of X-rays, he can make an intelligent estimate of the track and probable resting-place of the foreign body and if there are no more than minimal signs of intra-abdominal perforation. Foreign-body fragments may lodge in the liver kidney per-renal tissues, para vertebral gutters, buttocks, or perineum without having penetrated the peritoneum. In such circumstances operation should be withheld if there are no signs of peritoneal irritation. It is in such cases that the presence of peristaltic sounds fortifies the resolve to adopt conservative treatment. In a recent series of 33 patients so treated only 3 died—a much lower mortality than would have been expected if exploratory laparotomy had been performed.

Penicillin

In belly cases, penicillin is still in the experimental stage. Some of the complications—pneumonia, pelvic and subphrenic abscess, peritonitis, and wound infection—are usually caused by penicillin-sensitive organisms: therefore, it is rational to use penicillin, since the drug is now in abundant supply. Many surgeons think its use has been a potent factor in reducing chest complications and wound sepsis. The present dosage is 15,000 Oxford units 3 hourly for 7 days or 100,000 units in 500 c.c. of normal saline every day for 7 to 10 days by continuous intramuscular drip (4).

Evacuation

Abdominal cases travel badly by sea or air even when the wound has healed. Almost all cases are now held for at least 10 days before being moved from the Advanced Surgical Centre, and this should be the routine. If the laparotomy wound goes septic, they should be held until the wound is clean.

Fig. 15 General Edward M. Packenham, commander of the British forces at the Battle of New Orleans, who died from a wound involving the common iliac artery.

"Delayed suture of other wounds"

Abdominal wounds are very often accompanied by wounds of the limbs. The patient is not really fit for a second anaesthetic about the third or fifth day which is the ideal time for the delayed suture of these wounds. One solution of this problem is to insert stitches at the first operation but to leave them untied until the wound is ready for closure.

NOTABLES IN AMERICAN HISTORY WHO WERE VICTIMS OF PENETRATING ABDOMINAL GUNSHOT INJURIES

Because a number of notables in American History were the victims of penetrating abdominal gunshot injuries the writer believes that a brief review of the most outstanding of these cases should not only prove interesting but likewise very important from the historical point of view. Sev-

Fig. 16 William Beaumont collecting gastric juice from the stomach of Alexis St. Martin

eral other cases involved rather important persons of the day but those have not been judged as of sufficient historical importance to merit consideration in this particular presentation.

As far as the writer has been able to determine no conspicuous person in American history has ever been the victim of assassination by stabbing and certainly none by an abdominal stab wound. Each of the individuals herein considered was the victim of an abdominal gunshot injury and true to the traditions of this type of injury all died except one. Lincoln was shot in the head, and Anton J. Cermak the late and lamented Mayor of Chicago who received the bullet intended for our late and beloved President Franklin D. Roosevelt, was shot in the right side of his chest but died of general peritonitis. Accordingly these 2 cases have been excluded from this study.

General Edward M. Packenham

The case of a "Major King of the Fusiliers (43) who was killed at the Battle of New Orleans, is herein considered because this British officer

Fig. 7 President James A. Garfield.

was the victim of a musket-ball which struck him on the pit of the stomach leaving only the appearance of a contusion, apparently in the same manner as a blow from the hand of a pugilist on the same part." Of much greater interest, in this battle, is the death of Major General the Honorable Sir Edward Michael Pakenham, commander of the British forces, who received an abdominal wound involving the common iliac artery which "killed him on the spot. This casualty very probably had much to do with the ultimate outcome of this important engagement.

Alexis St. Martin

It took a penetrating abdominal gunshot injury, in addition to the perseverance, foresight, and good fortune of a young United States Army Surgeon, to win undying fame for Alexis St. Martin, an otherwise unknown young Canadian trapper who under less favorable circumstances would have been doomed to oblivion. When St. Martin was accidentally shot on June 6, 1822 little did he realize what an important contribution he was to make to our knowledge of the physiology of the stomach, and little did William Beaumont (82) the young Army surgeon who has himself been labeled one of humanity's great benefactors, realize that this single case was to win for him immortality in the annals of medical history.

The wound suffered by St. Martin, as the result of the accidental discharge of a musket loaded

with "duck shot," was an abdominothoracic type of injury which opened the upper left side of the abdomen and the lower left side of the chest. The whole load struck the victim from a distance of 2 or 3 feet and carried away an area of tissue larger than the size of the palm of a man's hand. Beaumont who arrived a few minutes after the accident noticed that the load had struck St. Martin tangentially tearing away parts of the fifth and sixth ribs, and leaving a large opening in the peritoneal cavity with protrusion of the lower lobe of the left lung from the thoracic cavity. The stomach was lacerated and there was much devitalization of the overlying and surrounding tissues. Because of these injuries Beaumont considered any attempt to save the victim a life as entirely useless. Accordingly, since he was unable to replace the lung properly he took out his penknife and cut away the excess. Then he applied a superficial dressing and left, expecting the victim to die in 20 minutes.

On his return, to his great astonishment and amazement, he found St. Martin still alive. After removal to more suitable quarters St. Martin was very ill for many days before he began showing evidence of recovery. Convalescence continued for many months, during all of which time Beaumont made every effort at his command to close the opening in the victim's stomach, which persisted in spite of all methods of treatment used. Since he was unable to close this opening, early in 1825 Beaumont conceived the idea of carrying out a series of experiments. However on several occasions St. Martin disappeared, usually not to return until after several months had passed. At times Beaumont became exasperated and almost frantic in trying to keep up with the movements of his patient. Finally he was able to complete his experiments and he published his work in 1833. Alexis St. Martin lived, with this permanent gastric fistula, for nearly 60 years after the accident, dying in 1881 and outliving Beaumont, who died in 1853 by 28 years. St. Martin died at the age of 78 years.

President James A. Garfield

At 9 30 in the morning on July 2, 1881, shortly after entering a railroad station in Washington, D. C. President James A. Garfield (89) was approached by Charles J. Guiteau a Chicago attorney who shot at the President twice before he was stopped and apprehended. The first of the bullets from the assassin a revolver struck President Garfield in the right arm, producing a slight flesh wound. The second bullet entered the right side of the back, four inches to the right of the spinal

Fig. 18. Course of the bullet in the case of President Garfield. The diagram shows how the bullet fractured the right eleventh and twelfth ribs posteriorly, passed through the first lumbar vertebra and grazed the splenic artery and resulted in an aneurysm which upon rupture caused death (From Med. News, 1882, 40 678.)

column and on a level with the twelfth the lowest of the dorsal vertebrae, and passing at first forward fractured the eleventh and twelfth ribs, then deflected to the left, passed through the body of the first lumbar vertebra in an oblique direction to the left and emerging thence, passed behind and below the pancreas where it was found at post mortem examination. The second bullet in its course penetrated some of the branches of the mesenteric arteries and grazed the splenic artery.

Thus injured the President was returned to the White House where he was treated conservatively according to the customs of that day by a group of eminently capable surgeons. The wound in his back was probed several times he was fed small quantities of liquid foods usually by rectum and occasionally by mouth opium was used for pain and among the other discomforts, he had to endure the annoyance of a hot and stifling summer heat. When the end finally came, the President who when shot weighed 210 pounds, probably did not weigh more than 135 pounds.

On September 6 after several requests by their noted patient the surgeons in charge permitted removal of President Garfield from the White House to the Franklyn Cottage in Elberon New Jersey. His convalescence at Washington had been rather stormy and very trying both to the patient as well as to the attending physicians. When removed to Elberon he appeared to have improved somewhat and it was felt that the sea shore surroundings would hasten his recovery.

Fig. 19. Diagram showing the course of the bullet through the first lumbar vertebra in the case of President Garfield (From Med. News, 1882 40 678.)

However he continued to run fever and no additional improvement was noticeable as the days went by. On September 19 1881 at 10 35 in the evening President Garfield died suddenly.

At the autopsy (99) it was found that death had resulted from a ruptured aneurysm of the splenic artery. It was conjectured that the bullet had grazed the splenic artery producing a weakened area that resulted in the fatal aneurysm. The course of the missile was traced through the first lumbar vertebra, and the bullet was found in the abdominal cavity among the intestines (99) which had been removed early during the post mortem examination.

Most of the best surgical opinions of the time were in agreement with the manner in which the President's injuries were managed. However Sims, who was in Europe at the time, apparently permitted publication of interviews in which he said the President should have been celiotomized. Sims contemporaries, generally were not in accord with this opinion and some felt he should have refrained from allowing the publicity given his interviews.

President William McKinley

Late in the afternoon of September 6, 1901 while receiving the public in the Temple of Music at the Pan American Exposition (92) in Buffalo New York President William McKinley was shot twice by Leon F. Czolgosz, who approached the President with his right hand wrapped in a handkerchief in which he held the pistol. As the President went to shake the assassin's left hand the latter fired the first shot which struck the victim tangentially in the midsternum, only grazing the area and failing to enter the chest. The second bullet fired immediately after the first entered

Fig 80. President William McKinley (Buffalo M. J. 90 907, 57 7 (N.S. 41)

the abdominal wall 5 or 6 inches below the left nipple and about 2 inches to the left of the median line." The assassin was stopped from doing further damage, and in a very few minutes the President was placed in the hospital on the Exposition grounds.

Shortly after the injury the President was operated upon by M. D. Mann who was assisted by a group of other prominent surgeons. Many difficulties were encountered during the operation. In the first place, the hospital's facilities were not entirely adequate and there were not sufficient instruments for the celiotomy. Then there was the huge size of the victim which made adequate exploration very difficult. Finally as the operation was being completed the setting sun removed the best source of light, and an assistant surgeon was compelled to use a mirror with which he reflected the setting sun's rays into the operative field. When the operation was completed President McKinley was removed to the home of Mr. Millburn, President of the Pan-American Exposition.

The operation lasted 91 minutes. The surgeons first discovered a perforation of the stomach and the opening in each wall was closed with continuous sutures. This required much time, mainly because of the President's size and the other difficulties already mentioned. Closure of the opening in the posterior wall of the stomach was accom-

plished by opening the lesser peritoneal sac, which made this part of the operation very difficult. It was at about this time that the President's condition appeared to grow worse, and did not warrant continuation of the operation. Accordingly it was stopped, the abdomen was closed, the wound dressed, and the patient transferred to Mr. Millburn's home in an ambulance.

Treatment of President McKinley continued very energetically at the Millburn home. Several prominent surgeons, among them Charles McBurney were called in consultation. A number of special nurses attended to the President's needs. After several days it seemed he would recover. However toward the end of the week his condition grew worse and then went steadily and rapidly downhill. He died on September 14, 1901 at 2:15 in the morning.

The autopsy performed by H. R. Gaylord, showed, in addition to the abrasion of the chest, perforations of the anterior and posterior surfaces of the stomach, which had been sutured a peculiar and not fully explained condition of the superior surface of the pancreas, near the tail, which was possibly the result of injury by the missile and probably had much to do with the fatal termination of the case, a slight laceration of the superior pole of the left kidney and possible injury to the left suprarenal gland.

Senator Huey P. Long

The late Senator Huey P. Long's importance in American History is based essentially upon the new and extraordinarily peculiar philosophy with which he had aroused the interest of the entire country at a time when the United States was still very unsteady as the result of the devastations of a depression unparalleled in the history of this nation. This philosophy had made him a national figure of great prominence and his untimely death cut short a career which many believe would have meant much progress for the United States. On the other hand, many were of the opinion that he was a demagogue of unusual ability and some felt certain that America was heading for a dictatorship with him as the dictator.

Because Senator Long was the victim of a penetrating gunshot wound of the abdomen, it has been deemed proper to include this case with the others briefly outlined. Thus far the writer has failed to find any report of this case in the medical literature. It is firmly believed that nothing of the case's surgical history has been published, except the incomplete and unreliable newspaper medical accounts of this tragedy. As none of

these have appeared sufficiently authentic to be reliable the writer has had to contact each of the physicians who supervised, or in any way assisted in, the treatment administered. Dr. Arthur Vidrine, who was in charge of the patient but unable to give access to the hospital record nevertheless discussed the case with the writer, who immediately afterward made notes of the necessary and important facts. Brief accounts of the surgical facts in the case were likewise given the writer by Drs. William H. Cook and Cecil O. Lorio, each of whom assisted preoperatively, as well as at the operation, and each of whom saw the Senator after the operation. A questionnaire sent to 'Our Lady of the Lake Sanatorium, where Senator Long was treated, was adequately filled out and returned to the writer.

Although many in Louisiana are of the belief that Senator Long was the victim of a bullet wound received at the hands of his 'panicky' bodyguards (50) during the scuffle which followed the approach of Dr. Carl A. Weiss toward Long, many others are nevertheless of the opinion that it was a bullet from the .32 caliber Spanish make automatic in the hand of the young doctor which entered the body of the Senator. Be that as it may, the fact remains that Senator Long was shot in the corridor of the Louisiana State Capitol at about 9:30 on Sunday night of September 8, 1935, as he left the Governor's Office.

The bullet which struck Senator Long entered just below the border of the right ribs anteriorly, somewhat lateral to the midclavicular line. The missile perforated the victim's body making its exit just below the ribs on the right side posteriorly and to the inner side of the midscapular line, not far from the midline of the back.

Upon realizing the extent of his injury the Senator in company with several friends hurried downstairs, got into an automobile and was driven to the hospital, which was only a few blocks away. There arrangements were made for an emergency laparotomy with Vidrine in charge. While preparations were being made Lorio assisted in the preoperative management and watched the pulse and blood pressure. Shortly after the victim's arrival in the hospital he went into profound shock and presented clinical evidence of internal hemorrhage. Finally when the systolic blood pressure dropped to about 90 and the pulse rate climbed above 110 the Senator himself said, 'Come on let's go be operated upon' (31).

Under ether anesthesia the abdomen was opened by an upper right rectus muscle-splitting incision. Very little blood was found in the peritoneal cavity. The liver, gall bladder, and stom-

Fig. 21 The late Senator Huey P. Long.

ach were free of injury. A small hematoma, about the size of a silver dollar, was found in the mesentery of the small intestine. The only intraperitoneal damage found was a 'small' perforation of the hepatic flexure which accounted for a slight amount of soiling of the peritoneum. Both the wounds of entrance and exit in the colon were sutured and further spillage was stopped. The abdomen was closed in layers as usual.

The postoperative course of the case continued steadily on the downgrade. Evidence of shock and internal hemorrhage appeared to become progressively worse. Sometime shortly after the celiotomy, Dr. Russell Stone of New Orleans suggested catheterization and the urine was found to contain much blood. At this time Stone's opinion was that another operative procedure to arrest the kidney hemorrhage would certainly be fatal, and as a matter of fact advised against it. At about 1:30 on the morning of Long's death he was seen by Dr. P. Jorda Kahle, New Orleans urologist, who aspirated the right perirenal area and upon withdrawing pure blood very easily concluded that there was a massive retroperitoneal hemorrhage. By this time, there was evidence of a marked bronchorrhea, the patient was practically moribund and any further surgery was deemed most inadvisable. The continuous intravenous drip was stopped. Although each of several blood transfusions seemed to result in a temporary improvement it was usually not long again before the

blood pressure began to drop and the pulse to become weak. By early morning of September 10, it was very obvious that further treatment would be useless. Hence, in spite of all efforts by an excellent group of physicians and surgeons, the Senator's condition continued rather precipitously on the downgrade and he died at 4:06 in the morning on Tuesday September 10 1935 about 30 hours and 36 minutes after being shot.

Although Vidrine tried to get permission, Mrs. Long objected to an autopsy and consequently none was performed despite the fact that a New Orleans pathologist was on the scene and ready at the time of Long's death. Death undoubtedly resulted from uncontrolled hemorrhage and shock. Lóbio was later of the opinion that the renal vessels had probably been torn by the bullet in its course through the body. Certainly without the energetic postoperative treatment, especially the frequent transfusions of blood, death would have very likely supervened much sooner. Although no autopsy was performed the condition of the intra-peritoneal viscera and other structures, and the course of the bullet—which was rather unmistakable because of the entrance and exit points—pointed rather suspiciously to an injury of the right kidney and possibly of the right renal vessels as the source of the hemorrhage. The fact that Senator Long died in slightly more than 30 hours, in spite of an unusually large number of blood transfusions, would seem to indicate that the injury to the vessel, or vessels, which undoubtedly continued to permit the escape of blood as fast as it was administered, was quite large.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Congenital Impatency of the Nasolacrimal Duct.
DuPort GUERRY III and EDWIN L. KENNEDY JR.
Arch. Ophth., Chic., 1948, 39: 193.

The term congenital dacryocystitis, is a misnomer since the dacryocystitis merely results from stasis and the underlying condition is an impatency of the nasolacrimal duct. The lacrimal system usually becomes patent throughout in the eighth intrauterine month. Twelve instances of congenital impatency were noted in a consecutive series of 200 newborn infants—an incidence of 6 per cent. In 10 cases the epiphora first appeared between the tenth and twelfth day after birth but in 2 cases tearing was delayed 3 and 4 weeks respectively. Penicillin ointment instilled 3 times daily reduced the discharge, the conjunctival injection and the incrustation of the lids. In this series all cases cleared without probing, the longest interval being 5 months the shortest 3 weeks. Involvement of the left side was predominant.

In a later series 5 cases were observed in which the congenital impatency persisted after 6 months. Probing cleared the condition immediately. They advise the use of Bowman's No. 1 probe through the superior punctum. With slight upward rotation the probe finds its way into the sac and duct without forcing it. The inferior turbinate has been previously shrunk by adrenalin and after the probe has reached the nasal floor a submucous elevator is passed in the inferior meatus until the probe is encountered. A sharp metallic click should be heard and felt, unless the probe is covered with a cushioning layer of membrane. If such happens, the probe is vigorously rubbed with the elevator until bare metal is felt. After this the Bowman probe is passed through the inferior canaliculus in order to be assured of the patency of that structure.

JAMES E. LEBENSOHN M.D.

Fat Embolization Involving the Human Eye. MILO H. FRITZ and MICHAEL J. HOGAN. *Am. J. Ophth.,* 1948, 3: 507.

The greatest number of cases of fat embolism follow traumas of the soft parts of the body and, more particularly fractures of the long bones of the lower extremities. Nontraumatic causes, such as diabetes, childbirth, or injections of oily substances, are undetermined. The marrow fat, source of most emboli, usually is liberated from the cells by direct rupture, as in a fracture or by concussion from a blow. The vessels in the bones are held within the rigid haversian canals, and do not collapse following the injury; the liberated fat enters these torn vessels during or following the injury. This fat passes through

the venous system to the right side of the heart and pulmonary circulation, where fine emboli lodge in the capillaries of the lungs. Some of the fat may pass through into the general circulation and result in systemic emboli.

Two main forms of the disease may be encountered: the pulmonary—which may be either immediate, developing soon after the injury or delayed, commencing the third or fourth day; and the systemic—with more particular involvement of the nervous system, leading to restlessness, excitement, delirium, convulsions, and coma. Death occurs in from 2 to 6 days.

Reports of ocular findings are extremely rare. Only one case was found in the literature (Evans, 1940). Another case is reported by the authors.

After the explosion of a gasoline stove a 21 year old soldier sustained multiple compound fractures of the long bones of the ribs and pelvis, in addition to rupture of the bladder and was admitted to the emergency hospital in shock. After treatment of the latter an open reduction of the tibia fractures was performed. Immediately following the operation, the patient's condition was good. Suddenly the next morning, a very marked change took place. The patient was unconscious and reacted sluggishly to stimulation. Pupillary reactions were reduced. A flaccid paralysis of the arms, and a temperature of 101.5°F were noted. Coma continued until the time of death.

The ophthalmoscopic examination, under mydriasis, showed in the fundi some round and oval, white, subretinal exudates surrounding completely both maculae and following the course of the main vessels there were no hemorrhages. The macula in the right eye appeared cherry red. The diagnosis of fat embolism was made based upon the following considerations: (1) the presence of fat in the urine (2) coma in a man with multiple fractures (3) coma in a man without signs of intracranial pressure (4) an eye-ground examination which showed embolic phenomena involving the retinal vessels (5) multiple petechial hemorrhages of the skin and conjunctiva, (6) chest films revealing a cotton ball appearance in the parenchyma of the lungs. The patient died on the tenth postoperative day.

The general pathology protocol reported a generalized fat embolization and a terminal pneumonia. The ocular sections were stained with sodan IV. The examination revealed some diffuse edema and round-cell infiltration of the ciliary body. Several small capillaries showed fat emboli. Several vessels, just beneath the choriocapillaris and near the optic disc, contained fat emboli. The principal changes in the eye occurred in the retina. Scattered fine hemor-

rhages were noted in the nerve fiber and ganglion cell layers. Focal areas of secondary degeneration were seen in the inner portion of the retina and in and around these areas, the terminal arterioles and capillaries were dilated and contained fat emboli which stained with sudan IV. In some areas the capillaries had ruptured and fat lay in the retinal stroma. A number of capillaries of the optic nerve also showed fat emboli.

MICHEL LOUFAILLAH, M.D.

General Treatment of Conjunctivitis (Tratamiento general de las [conjuntivitis]) RAUL ARTURO CHAVIRA. *Anales med Mex.* 1947 8:1

There is no general agreement regarding classification of the various forms of conjunctivitis. The author divides the subject into contagious noncontagious septic atypical and that due to avitaminosis. These groups are again divided into numerous subgroups based mostly on anatomicopathologic findings.

Treatment of these various conditions is prefaced by a dozen rules of therapy founded primarily on general principles of eye therapy such as the use of cold compresses, guarding the orbit, the correction of systemic diseases and the use of sedatives.

The description of the treatment of the specific forms of conjunctivitis includes a discussion of mucopurulent purulent membranous granular follicular and pinnaveal types as well as those due to avitaminosis. Therapeutic formulas are given in each instance as well as general and special corrective measures.

STEPHEN A. ZIEGLER, M.D.

Denig's Operation for Trachomatous Pannus. N. PIERA. *Brit J Ophth.*, 1948, 31: 385

Denig's operation is suitable for the third or fourth stage of trachoma when the disease is nearly quiescent in the conjunctiva but still active in the cornea, as evidenced by progressive and stubborn pannus formation. It consists of resection of a strip of conjunctiva at the limbus adjacent to the pannus one half as wide and as long as the involved area. It is important that all of the tissue to the episclera be removed. The defect is then covered with oral mucosa fixed with silk to the conjunctival, but not corneal edges of the wound. The graft if it takes is pink and edematous at the first dressing and there is striking improvement in the clarity and appearance of the cornea.

The author discusses the rather considerable literature concerning the operation about which there is much controversy as to its benefit whether the mucosa forms an impenetrable wall against the invading trachoma and the fate of the graft.

Two cases are presented in which the operation caused improvement in a troublesome recurrent, trachomatous pannus. Histological study of the graft in one of these patients 12 years later showed the structure of mucous membrane slightly modified by stunting of the papillae and acanthosis. In another patient a tremendous serpygious ulcer occurring late

in the course of trachoma healed. Examination of the graft 19 years later showed the structure of mucous membrane. One case of trachomatous pannus aggravated by local irradiation was not improved by the procedure although the graft took.

The author recommends more frequent use of mucous grafts for any plastic operation of the trachomatous eye.

FRANK W. NEWELL, M.D.

Degeneration and Regeneration of Nerves in Corneal Transplantation; an Experimental Study. HUMBERTO ESCARINI. *Arch. Ophth. Chik.* 1948 39: 135

The corneal graft in rabbits is insensitive to a light cotton touch for the first few weeks after operation. This insensitivity is also found in the a mm of host cornea that surrounds the graft. Recovery of sensation was first noted at about the forty fifth day. The intensity of response gradually increased till about the seventieth day but never reached the normal threshold. Physiologic tests indicate that after keratoplasty 90 days is required for each millimeter of reinnervation.

When a corneal graft is cut the severed corneal nerves undergo wallerian degeneration. Degenerative changes are also observed in the nerves of the host cornea in an area of about 2 mm around the graft and in this area both the degenerative and the regenerative changes progress more rapidly. In 30 days the majority of axons are no longer recognizable. Elongated nuclei are seen lying in a clear halo which occupies the space left by the disappearance of the myelin sheath. The plasmatic sheath is defined by the sheath of Schwann to which these nuclei belong. There is complete granulation of the nerve fragments. In 60 days the axonic debris has completely disappeared the old nerves being reduced to empty tubes. Since no macrophagic reaction takes place one may assume that the disappearance of the axonic debris depends exclusively on the Schwann cells.

To enter the graft the outgrowing axis-cylinders must pass through the organizing connective tissue at the line of junction of the graft. At the scar growth proceeds slowly the regenerating axis cylinders taking a wavy course the majority finally growing into the Schwann sheaths left empty by the disappearance of the old axons. As the number of regenerating axis cylinders increases maturation takes place. This consists of an increase in the caliber of the axons and a realignment of the Schwann nuclei.

Reinnervation follows the same course in clear and opaque grafts but in the opaque graft maturation is slightly retarded. The regenerative changes eventually result in complete histologic innervation of the graft.

JAMES E. LEIBENSOHN, M.D.

Anterior Lentiglobus. An Atypical Case. K. SEM. *Brit. J Ophth.*, 1948 31: 305

The author presents a case of anterior lentiglobus an extremely rare condition in which the lens has a

small globular projection at the anterior pole. It consists of clear cortex only but the area becomes highly myopic and interferes with vision. The condition gets progressively worse and eventually an anterior polar cataract develops. The cause of the condition is not known. The anterior capsule of the lens may be weakened and allow herniation of lens cortex through the weakened capsule.

EARL H. MERR, M.D.

The Capsular Complications of Cataract Extraction
CHARLES GOULDEN *Proc. R. Soc. M. Lond.*
1943, 4 37

The author considers the capsular complications of cataract extractions and the best method of averting them.

1. The capsular remnant may become adherent to the operation scar and in some cases glaucoma results. The remnant should be detached early with a blunt-ended knife through a keratome incision.

2. Opaque capsular membranes or after-cataracts may be of several types: (a) opaque lens fibers imprisoned between anterior and posterior capsular remnants, (b) new gray lens fibers from proliferating subcapsular cells, (c) Elschnig's cells, (d) heavy thick membrane following hemorrhage and (e) thick membrane following infection.

The treatment may be any one of the following: (a) make a capsulotomy incision in the thin membrane avoiding thick bands, (b) double needle knives may be used if it is feared that pull and tug on tough membrane may cause trauma, (c) a Wheeler incision may be made or (d) a Ziegler needle knife may be used to incise a triangular hole in the capsule.

Care is taken not to penetrate through the posterior lens capsule and allow vitreous to mix with the lens material.

The author is firmly convinced that intracapsular cataract extraction will be a great help in reducing capsular complications.

EARL H. MERR, M.D.

Amblyopia ex Anopsia; a New Concept of Its Mechanism and Treatment. B. M. LAZARUS.
Irish Ophthalm. Soc. 1943, 30 83

According to the author amblyopia ex anopsia results primarily from deviation of the visual axis from the fovea to a point elsewhere on the retina where vision is less acute. If the patient uses the amblyopic eye to fix at a lighted ophthalmoscope bulb at about meter distance it will be apparent that the corneal reflex is eccentrically placed, the distance from the visual axis being proportionate to the degree of amblyopia. The field in the stereocomplimeter shows the blind spot in the amblyopic eye to be displaced in a direction that coincides with the displacement of the visual axis.

Treatment should aim at correcting the malprojection and restoring the true visual axis relationship of object to fovea. This is accomplished by exercises in eye-hand co-ordination. At first large white board is presented on which are pasted vivid red discs, which with successive treatments decrease in

diameter from 4 inches to $\frac{1}{4}$ inch. With the good eye occluded the patient attempts to place a thumb tack in the center of each disc. The tacks at the beginning are in variably outside the disc, and in the same relative position. To encourage eye-hand training the patient is permitted even to use his hands and feel his way into the disc. The next step is the copying of letters from a chart, pointing out each letter as copied. The illumination is by an intermittent flashing light and the letters become progressively smaller as the vision improves. After 20/70 acuity is reached, the training is combined with a variety of exercises for the development of fusion.

Almost any age group can be treated successfully. Among the cases cited is that of a woman aged 41 years, with 20/400 vision in the amblyopic eye. At her ninth treatment she had second degree fusion and an acuity of 20/25.

JAMES E. LEFENWORN, M.D.

Glaucoma. PETER C. KROSVITZ and H. ISABELLE McGOARRY *J. Am. M. Ass.* 1943, 36 957

The specific object of this study has been the establishment of the relationship between the course of the glaucomatous involvement of the optic nerve and the prevailing range of tension in the various stages of glaucoma. The report is based on the observation in the Glaucoma Clinic of the Illinois Eye and Ear Infirmary of definite (not borderline) cases of so-called primary glaucoma in adults. The classification as to the stage of the disease was based entirely on perimetric findings. Three stages (early, moderately advanced, and far advanced) were distinguished and somewhat modified from Glaucomatous three groups.

The report is based on 225 eyes with wide-angle and 100 eyes with narrow-angle glaucoma. The ratio of success to failure of miotics was 27 to 88 or 31 per cent of successes in the wide angle type, and 35 to 40 or 83 per cent in the narrow-angle glaucomas, which showed that the miotics were much more effective as tension lowering agents in narrow angle than in wide-angle glaucomas. The dramatic course of narrow-angle glaucoma is apt to scare the patient and surgeon into early operation which might have been made unnecessary by the application of stronger miotics. The chronic course of wide-angle glaucoma on the other hand is conducive to an attitude of procrastination on the part of the physician as well as of the patient especially if there is no rapidly progressive loss of field. This explains why 3 cases of wide-angle glaucoma were permitted to remain with tension not normalized for 3 years.

With regard to the results of surgical treatment the results in the two groups are probably better than expressed by the statistics: the ratio of success to failure being 31 to 6 in the narrow-angle, and 34 to 25 in the wide-angle glaucomas. The large majority of the operations in narrow-angle glaucoma were iridectomies. The reason for this difference between the two types of primary glaucoma in response to therapy lies in the difference in mechanism. There

is good evidence to the effect that in narrow angle glaucoma the trabecula canal of the Schlemm mechanism is and remains normal until the trabecular spaces are completely closed off from the anterior chamber by goniosynechiae. The aim of the treatment is to keep the trabeculae accessible to the aqueous which is easily accomplished with miotics or an iridectomy.

On the other hand in the majority of wide angle glaucomas the disturbance is probably due to impaired function of the trabecular canal of the Schlemm mechanism itself, and is therefore much more deeply rooted than in the narrow-angle glaucoma. Failure of miotics calls for an operation of the filtering type the success of which is still dependent on factors not completely understood and not entirely under the control of the operator.

In wide-angle glaucomas the course of the glaucomatous involvement of the optic nerve may be summarized as follows:

The eyes of stage 1 act as one would expect glaucomatous eyes to act, the course of the disease of the optic nerve showing a close dependence on the prevailing tension range and the independence of the relationship being rare enough to be considered an exception. In stage 2 the striking feature is the large percentage (38) of further progression of the glaucomatous involvement of the optic nerve (in this group in which tension was normalized surgically). In stage 3 the further progression of the disease in tension-normalized eyes was still greater (50 per cent). Twenty three per cent of the group in which the tension was not normalized showed the remarkable feature of endurance of high tension ranges without further loss.

In narrow angle glaucomas under conditions of non normalization, the glaucomatous disease progressed rapidly to total blindness. Under conditions of normalization the disease remained stationary during the 5 year period, and for longer periods in approximately 90 per cent of all tension normalized eyes, irrespective of the stage at which the normalization took place. Further progression occurred in less than 10 per cent of the normalized eyes of stages 2 and 3 which is a strikingly low percentage compared to the wide-angle glaucomas. Therefore it can be said that the later stages of glaucoma showed a strong tendency toward further progression of the disease despite normalization of the tension.

The type of operation that produced the normalization did not seem to be an important factor as the three main types of operation (corneosclerectomy, iridectomy, and cyclodialysis) were represented in about the same frequency in the surgically normalized eyes presenting further progression of the disease.

The very center of the visual field seemed to exhibit a specific resistance to glaucomatous disease. Its chances of survival (83 per cent) after normalization of tension were estimated and reported for the respective stages of the disease.

MICHEL LOUTFALLAH M.D.

EAR

Some Clinical Phenomena of Deafness in the Light of New and Old Tests of the Ear F. KORRAX
Arch. Otol. Chlc. 1948 47 113.

The author states that the otologist should test the hearing not only with audiometric tests but also with tuning fork and vestibular tests. These are especially important in the diagnosis of latent congenital deafness. The tuning fork tests which are important are:

1. Loudness test. The loudness of the patient's threshold for each individual tuning fork is estimated by the examiner.

2. Period hearing. The period during which the patient can detect a tone from each tuning fork is compared to the normal.

3. The audiometric provocative test. A loud audiometric tone is placed on the untested ear while a Rinne test is done on the opposite ear. The normal response on the tested ear is a negative Rinne test. This is because of the damping effect on air conduction, of contraction of the middle ear muscles.

The author offers the following definitions: hereditary deafness is defined as those cases in which the next of kin show manifest deafness and congenital deafness as those cases in which latent abnormality of the genes can be detected by special methods of diagnosis. In congenital deafness the audiometric examination and loudness with tuning forks may be normal. However, period hearing with the 1,024 and 2,048 tuning forks may be less than one half normal. Audiometric provocative tests may show a positive Rinne test instead of the normal negative Rinne test. Vestibular abnormalities are not infrequent.

An explanation is offered also for the false Rinne test in which a totally deaf ear manifests a negative Rinne test. It is believed that the apparent hearing by bone in the deafened ear is due to a cochleovestibular sensation because of some vestibular directional sensitivity. The older explanation of Shambaugh was that the hearing was tactile sensation via the trigeminal nerve. The author cites an experiment to support his contention. A medium intensity audiometer tone (d7) is placed on the deaf mastoid. A loud tuning fork of a different frequency (ex) is placed on the normal mastoid. The patient's sensation consists of the loud tone on the normal ear first, then two different frequencies lateralized to the middle of the head and finally as the tuning fork dims the only sensation is the medium tone of the audiometer in the deafened ear. WILLIAM K. WRIGHT M.D.

NOSE AND SINUSES

Intranasal Extension of Sellar and Parasellar Neoplasms. STANTON A. FRIEDBERG. *Laryngoscope* 1948, 58 347.

Neoplasms arising in and about the sella turcica may involve the sphenoid sinuses, nasopharynx, and nasal cavities. The most common of these are the

pituitary adenomas and chordomas. In the 3 cases presented the diagnosis of the type of lesion was made by microscopic examination of tissue removed from the nasopharynx or nasal cavities.

Headache primary optic atrophy bitemporal hemianopsia, and alterations in the roentgenographic appearance of the sella turcica are characteristic of pituitary tumors. Chromophobe adenomas, comprising from 80 to 90 per cent of all pituitary tumors, produce generalized adiposity, diminution of secondary sexual traits fatigability a lowered basal metabolic rate and an elevated sugar tolerance. Nasal obstruction postnasal discharge and occasional blood streaked sputum are the most common symptoms of nasopharyngeal or nasal extension of the tumor.

Complete removal of the tumor is impossible. Irradiation with roentgen rays and radium, or transfrontal, trans-sphenoidal, and paranasal surgical removal, alone or in combination, all have adherents.

Chordomas have their origin in vestigial remains of the fetal notochord. Cranial chordomas usually begin at the junction of the sphenoid and occipital bones in the region of the sella turcica. The microscopic picture is extremely variable. One of the diagnostic features is the presence of large vacuolated hyperchromatic cells. The signs and symptoms are those of a brain tumor or nasopharyngeal growth with headache ocular disturbances, nasal obstruction or discharge and epistaxis.

Radium and roentgen therapy are of no proved value for chordomas. Local recurrences are common however palliative relief may be achieved by removal of accessible tumor by surgical diathermy.

All patients with suspected anterior or middle cranial fossa tumor should have a careful nasopharyngeal examination. The necessity for microscopic study of all nasal polyps is again emphasized.

JOHN R. LINDSAY, M.D.

Benign Cysts of the Antrum. Originating from the Jaw or Teeth. W. A. NEWLANDS. *Laryngoscope*, 61:3, 58: 402.

Radicular cysts and dentigerous cysts arising from the teeth may enlarge to encroach upon the maxillary sinus.

The radicular or root cyst has its origin in a root granuloma. The granuloma develops secondary to pulpitis. Cyst formation proceeds by dissolution of the center and connective tissue proliferation of the periphery of the granuloma. Further enlargement results in erosion of alveolar bone and invasion of the antrum.

Dentigerous cysts develop from the tooth sacs of retained or supernumerary isolated tooth germs. They develop around the crown of the tooth and may contain one or more deformed teeth projecting into the cyst space. These cysts have a dense fibrous tissue wall with areas of thin, shell-like bone, and a compact epithelial lining.

The surgical procedure found to be successful in the 2 cases presented was as follows:

The anterior wall of the maxillary sinus was exposed and opened through the canine fossa approach whereby the cyst was opened. The cyst lining was removed completely except that a portion of the floor was left undisturbed if its removal seemed liable to create a fistula through the palate or to disturb the blood supply to the adjacent teeth. A large nasointral window was made. JOHN R. LINDSAY, M.D.

MOUTH

Langer's Lines and Facial Scars. LEOGARD R. RUTHER. *Plast. Reconstr. Surg.* 1943, 3: 147.

The author emphasizes the importance of skin flaps for obtaining fine linear scars. It has been pointed out that an elective incision in direction with the lines would heal with little scar. Heretofore, the explanation was two-fold: a scar parallel to the lines would be inconspicuous because it resembled a line. The other explanation was the misunderstood thought that Langer's lines ran in the same direction as the muscles, avoiding pull on the wound edges. The first explanation holds, but the second does not. Actually the muscle pull tends to separate the wound edges, widening the scar. This fact must be understood if cosmetic surgery is a prime factor. A scar against skin lines stands out prominently. Knowing the danger of muscle pull, the surgeon can take measures to overcome it by very careful suturing and postoperative care. Briefly outlined, the important things to remember in obtaining a fine scar are: (a) the suturing of all deep tears in layers (b) placing superficial subcutaneous sutures to take all tension off skin edges (c) putting the finest sutures very closely together in the epidermis and removing them no sooner than 3 days. Since active healing is only starting at that time, the wound edges should be held by collodion strips (fine mesh gauze fastened by collodion across the wound edge). These strips should be applied and reapplied for at least 3 weeks, preferably 3. Constant care to have anatomical parts at rest to avoid muscle pull, should be observed.

LOUIS T. BYARS, M.D.

NECK

Proteolytic Activity in the Physiology Pathology and Therapeutics of the Thyroid Gland. Van Meter Prize Essay E. DE ROBERTIS. *West. J. Surg.* 61:3, 56: 333.

The thyroid gland stores its secretion inside the follicular cavity as a colloidal substance containing thyroglobulin, and the secretion released into the circulation is a continuous process, the velocity of which is governed by the organism's needs. With the freezing-drying technique, the author demonstrated that cytological products of secretion are located within the cells and reabsorption is always intracellular. Since, however thyroglobulin is actually a macromolecule its passage through the follicular epithelium cannot be explained on the basis of the ordinary concepts of cell permeability.

The author therefore tested the presence of proteases in the colloid extracted from single follicles of the rat thyroid. Under magnification and with micropipettes guided by a micromanipulator a proteolytic enzyme which digests a gelatin substrate, was obtained. Its activity was found to be increased in the acid range and diminished in the alkaline. Similarly after the injection of thyroid stimulating hormone proteolytic activity was heightened and after prolonged iodine administration it was decreased. The determination of the pH of the follicles by the microinjection of indicators showed no marked changes after the administration of thyroid stimulating hormone or iodides which could explain the variations.

This led the author to propose the theory of enzymatic reabsorption which postulates that enzymatic hydrolysis of the thyroglobulin into a product of lower molecular weight (probably an iodized polypeptide) makes possible reabsorption by the cells. Theoretically it may be that the proteolytic enzyme is also involved in the synthesis of thyroglobulin.

The degree of proteolytic activity of normal and pathological human thyroid tissue was measured photometrically by determining the amount of liberated tyrosine and tryptophane on an edestin substrate at pH 4 and expressed as milligram equivalents of tyrosine per 100 mgm of tissue. Under arbitrarily fixed conditions the proteolytic activity of 10 normal glands yielded on the average 0.444 mgm. Under the same conditions in 11 severe toxic goiters the proteolytic activity was found to be about 96 per cent above that of the normal gland. In 5 cases of nodular toxic goiter a difference of at most 100 per cent was found between the proteolytic activity of the adenoma and that of the surrounding thyroid tissue. In 7 simple diffuse colloid goiters there was a decrease of proteolytic activity corresponding to 27.9 per cent of the normal. In 7 mild cases of toxic goiter in which the symptoms including the elevated basal metabolism rate were rectified by treatment with iodine, the proteolytic activity was decreased to about 26 per cent below the normal level. This led to the conclusion that the proteolytic system may play an important role in the physiopathology of toxic and simple colloid goiters.

That inhibition of proteolytic activity is the basis for the therapeutic effect of iodine is suggested by the results of experiments on rats and in mild toxic goiter. This may be due to an inhibition of the release of the colloid as well as of hormonal synthesis. In vitro studies indicate that direct iodization of the proteolytic enzyme may be the mechanism responsible for the inhibition. Similarly, radioactive iodine was found to inhibit the formation of diiodotyrosine and thyroxine.

Thiourea has no action on proteolytic activity but acts on a totally different mechanism inhibiting the enzymatic system involved in iodization. It is suggested that the effectiveness of iodides, when given with thiocarbonyls, may be due to their interference with the action of thyroid stimulating hormone.

DAVID H. LYNN, M.D.

The Effect of Sex Steroids on Experimental Goiter and Iodine Storage in the Thyroid. F. X. GARNER, H. W. BARRETT and R. G. GUSTAVSON. *West J Surg* 1948 56 346.

The authors review the literature on the interrelationship between the thyroid ovary and pituitary and conclude that experimental results are inconclusive and contradictory because of the elasticity of the physiological equilibrium in the normal animal, which makes it difficult to demonstrate mechanisms of inhibition or stimulation. The authors postulate that if a given organ can first be unbalanced by imposing stress then subsequent inhibition or stimulation of that organ can be produced more easily. Experimental work is reported in which the effects of gonadal hormones on the thyroid were studied after the thyroid was subjected to stress by maintaining the animal on a goitrogenic diet.

In the first experiment 30 micrograms of estrone were injected daily over a period of 12 weeks into normal female rats 8 weeks of age which were fed a moderately low iodine goitrogenic diet. There was a highly significant decrease in the iodine content of the thyroid glands, the mild goiter occurring on the control diet was alleviated, the pituitary weight was doubled, and exophthalmos occurred unexpectedly in all of the rats after the third week of injections.

In the second experiment 40 micrograms of testosterone propionate were injected daily over a period of 12 weeks into normal and castrated male rats 26 weeks of age which were fed a low iodine goitrogenic diet. There was a highly significant decrease in thyroid iodine content in the normal animals and a nearly significant decrease in the castrated ones. Control castrated animals showed partly goitrous and partly atrophic thyroid parenchyma with follicular degeneration. These changes were alleviated with testosterone. Pituitary enlargement following castration did not respond.

The writers suggest that pituitary hypertrophy in estrone treated females is compensatory as a result of interference with either the production, secretion or utilization of thyrotropin by excess estrone. This pituitary hypertrophy was not seen in intact males despite a significant reduction in the thyroid iodine and a slight alleviation of the goiter. Therefore the mechanism responsible for thyroid depression in the female either is not the same as in the male or it is activated to a different extent.

S. LLOYD TRITHELMAN, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Intracranial Aneurysm of the Internal Carotid.
Operation. Cure (Aneurisma intracranialis de la carótida interna. Operació Curado.) GRACIA HUGO DICKEMAN, LUDWIG ZIMMAN and ALFREDO M. ZELASCO *Cirurgi* 947 44

A 46-year-old, white woman awoke at 4 a.m. with intense pain in the left frontal and parietal regions. Ten minutes later blepharoptosis and amaurosis occurred on the left side. Examination disclosed also left sided anisocoria papilledema anesthesia of the trigeminal region and paresis of the oculomotor trochlear and abducens nerves. During the preoperative stay in the hospital the ptosis diminished and vision improved and the eye regained partial movement (inward rotation). However the pupils persisted and ear noises developed on the affected side. The condition was recognized as the syndrome of Rollet (paralysis of the second third, fourth fifth, and sixth cranial nerves) and under the diagnosis of intracranial aneurysm of the left internal carotid the artery was ligated by the technique of Dandy. It was ligated first in the neck. 8 days later a left temporal flap of the skull was lowered and a silver clip was applied to the internal carotid artery where it was easily accessible alongside the optic nerve.

As the middle cerebral cavity was exposed the cerebral tissues were observed to be under tension the optic nerve was elevated and the artery at this point was dilated with abnormal congestive conditions about it, so that it did not have its normal appearance but seemed to be inclosed in a thick mesh of congested vasa vasorum vessels.

Following the operation the symptoms of increased intracranial tension decreased immediately and the headaches became less severe the mental condition of the patient returned to normal, and she was able to resume her occupation. The trigeminal anesthesia persisted and the eye movements did not entirely return to normal the internal rotation has persisted and will be the object of eye-muscle surgery.

The authors think that this is the first instance of this condition with a successful surgical outcome in Argentina, and offer the report merely as an addition to the statistical material on the subject.

JORDAN W. B. EMMAN M.D.

Cerebellar Abscess, Acute, Otolgic \ ASSAFEROU
J. Lar. Otol. Lond. 948, 62: 78

This extraordinary article is the report of 3 cases of cerebellar abscess. The author apparently reported 4 consecutive successful cases in 1913 thus making 7 consecutive cases of cerebellar abscess. Two additional cases are reported to illustrate what may happen to cerebellar abscesses. The present 3 case reports substantiate the previously reported 4 cases.

The article consists of day-by-day reports and progress notes of these 3 cases.

The article opens with a discussion of early diagnosis of cerebellar abscess and a differential diagnosis between cerebellar and temporoparietal abscesses, and the following assertions are made:

1 When the cerebrospinal fluid pressure in the tranquil patient was below 200 mm. of water the suspected brain abscess was below the tentorium (cerebellar).

2 When the pressure was above 300 the abscess was above the tentorium.

The cases since encountered confirm the postulates previously adumbrated.

It is believed that the most important sign however is persisting nuchal rigidity which is regarded as the keystone of early diagnosis. Nystagmus and arm symptoms are next in order of importance. The invariable sequence is described as persisting nuchal rigidity and with the onset of dyadiadokokinesis the diagnosis becomes certain.

The author believes that these cases should not be abandoned to the neurological surgeon. Early drainage once the abscess has been diagnosed is emphasized.

ABRAHAM VIER BRUNOWITZ M.D.

Pinealomass (Pinealomas) JOSE BENJAMIN DIA MÉRICA,
B. Air 948 for 430.

The frequency of these neoplasms is not great however they should not be considered exceptional.

The pathological forms are as follows: pinealoma spongiosoblastic, malignant pinealoma, teratomas or teratoid fibromas, sarcomas, gliomas, gliosarcomas, neurogliomas, neuroepitheliomas, carcinomas, adenomas and cholesteatomas.

The symptoms produced by these tumors may be classified into the following groups: (a) intracranial hypertension (b) localization symptoms, (c) endocrine and (d) typical. Radiological signs are present.

Intracranial hypertension is due to the occlusion of the Sylvian aqueduct by the tumor this results in an internal hydrocephalus which causes papilledema.

The symptoms of localization are ocular disturbances, impaired hearing due to the involvement of the posterior quadrigeminal tubercles and the lateral lemniscus, motor disturbances from pressure on the pyramidal tract in the medulla which produce weakness in one or both extremities, asymmetry from pressure on the superior cerebellar peduncles, and symptoms of diabetes insipidus from invasion of the third ventricle.

Endocrine involvement results in an increase in size with sexual precocity before puberty increase in pubic hair adult voice, and mental precocity.

Röntgenograms may show calcification of the gland with displacement. Pneumoventriculography

is of help in visualizing any obstruction to the aqueduct, while ventriculography is of some value. However arteriography is of minor importance.

The situation of the pincal mass rather than their histological type makes the prognosis very grave.

Treatment is surgical, radical, or the combination of both. When the incision is made over the tumor the excision is accomplished either through the corpus callosum or transventricularly. In the indirect intervention either a decompression or a derivative type of intervention with re-establishment of the circulation of the cerebrospinal fluid is used.

The author reports 2 cases of pinealoma. In the first case the symptoms were typical with an early hypertensive syndrome a pseudo-Argyll Robertson pupil, bilateral mydriasis the syndrome of Parinaud asynergy of the trunk, involvement of the fifth sixth ninth, and twelfth cranial nerves and cerebellar symptoms. X-ray examination revealed intracranial hypertension while ventriculography revealed a large bilateral hydrocephalus.

In the second case there was some increased sexual development in a 17 year old male having the syndrome of Parinaud Argyll Robertson pupil and intracranial hypertension. The surgical result was good.

ARTHUR F. CIRIELLO, M.D.

Diploic Epidermoid and Extradural Pneumatocoele

Cranial Defects and Deformity. JOSEPH E. J. KIRO, *Ann Surg* 1948, 127, 925.

Two uncommon types of cranial defects are discussed and detailed case reports of 4 patients operated upon by the author are presented. Diploic epidermoid and extradural pneumatocoele of spontaneous origin each have a characteristic appearance in the roentgenogram and should be diagnosed before operation. The neurological findings roentgenographic diagnosis and operative technique are presented for each of the 4 patients. Reproductions of roentgenograms as well as photographs of the patients and the surgical specimens clarify the text.

Diploic epidermoids usually destroy the inner table of the skull and may perforate the dura before the outer table is destroyed. Islands of bone in the outer table represent areas in which bony destruction is not complete, and a dense white scalloped margin with bone destruction is characteristic on roentgen examination. The tumor does not invade the bone but destroys by compression. The mass may occupy a relatively large amount of intracranial space compared with the smaller diameter of the defect in the skull. The involved bone should be resected and if the dura has been perforated a fascial transplant may be necessary. If the dura is not resected the bone block may be reinserted after curettage and boiling of the bone segment. Repair of the bony defect should be deferred for several months in patients with larger defects in whom dural resection and fascial transplant is necessary.

Extradural pneumatocoele of spontaneous origin without perforation of the skull is discussed and 2

cases are presented. The position of the internal peering of the air fistula sometimes is not known preoperatively. The author states that no other lesion produces such a coral rocklike pecture of the skull. Unven erosion of the skull occurs as a result of the air pressure and in some places the skull is almost completely destroyed. The dura is usually adherent to the depressed cortex and the author cautions against attempting to fix the dura to the bone. The involved segment of bone should be resected. After removing the bony spicules of the segment it may be used to repair the cranial defect. The intracranial extradural opening of the air fistula should be found and closed with a fascial or muscle fascia transplant.

JOHN L. BRIT, M.D.

PERIPHERAL NERVES

Cervicobrachial Pain. C. E. HADGART, *J Am M Ass* 1948, 135, 505.

Twenty patients with neck and arm pain were studied and divided into 2 groups: those with abnormal x-ray findings and those without such findings. The patients with the abnormal findings revealed cervical rib (3), cervical disc (3), degenerative arthritis (3), and cervicodorsal scoliosis (1).

The patients who revealed no abnormal x-ray findings presented the scalenus anterior syndrome (4), the costoclavicular syndrome (3), and the hyperabduction syndrome (3). In one case the symptoms developed following trauma.

The method of treatment consisted in correcting vitamin B deficiency, the result of inadequate diet by the administration of vitamin B complex three times daily. Mild analgesics were also used and finally faulty posture and occupational habits were corrected.

There is a short reference to some of the authors who have in the past contributed to the understanding of this type of pain and there is reference to Wright's work on the hyperabduction syndrome. There is also a short bibliography.

ARTHUR A. BRUNNEN, M.D.

SYMPATHETIC NERVES

Raynaud's Phenomenon and Atypical Causalgia: the Role of Sympathectomy. ERIC J. KESSLER, *Ann Surg* 1948, 127, 720.

The author limits his report to the role of sympathectomy in Raynaud's disease and atypical causalgia states. These conditions are characterized by marked vasospasm without obliteration of vascular channels. He interprets the presence of hyperhidrosis, coolness, cyanosis, cold sensitivity, and color changes as indicative of vasospasm. He believes the mechanism of vasospasm to be neurogenic and examines for it objectively by regional procaine block of the sympathetic ganglia. For the upper extremity, block of the stellate ganglion with 10 c.c. of one half per cent procaine is done and for the lower extremity a single injection of 30 c.c. of one half per cent pro-

caloe is introduced through a 7 inch needle placed at a 40 degree angle to the sagittal plane in the region of the second and third lumbar vertebrae. Skin temperature determinations and clinical observations are made before and after sympathetic ganglion block.

A total of 30 cases of Raynaud's phenomenon were seen. Five of the patients were operated upon. The operations were preganglionic cervicodorsal sympathectomy and lumbar preganglionic sympathectomy. They were completely successful in 4 of the patients and only partially successful in the other patient. The author believes that a conservative attitude toward the surgical treatment of Raynaud's disease is proper and that sympathectomy should be done only in severe and rapidly progressive cases with sclerodermatous and ulcerative changes.

Sympathectomy has been successful for atypical causalgic states in which the pain does not limit itself to the anatomic distribution of an involved nerve for patients in whom there has not been a long history of edema in the lower extremities, and for those who have a marked sensitivity to cold.

DANIEL ROGÉ, M.D.

MISCELLANEOUS

Myocardial Infarction Resulting from Surgical Removal of the Stellate Ganglion in Angina Pectoris (L'infarctus du myocarde accident de la stelléctomie dans L'angine de poitrine) D. DANIELOPOLU
Presse med. 945, 36-337

Evidently Danileopolu warned, as early as 1932, that removal of the stellate ganglion for the relief of pain in angina pectoris would be fraught with dangerous consequences. This article is based on the work of others reported in the literature but principally the paper of Lindgren and Olivecrona in the *Journal of Neurosurgery* in 1947. Lindgren and Olive-

crona operated on 71 patients with angina pectoris selected from a group of 250, the operation consisting of the removal of the upper four thoracic and the inferior cervical ganglia. In a large proportion of the cases the operation was bilateral. Three patients died during operation and 8 developed myocardial infarction in the first 30 days after operation; 3 of the latter died. Thus, Danileopolu states that 15 per cent of the patients treated surgically for angina sustain myocardial infarction because of this operative procedure. He considers that the article of Lindgren and Olivecrona supports and in fact establishes, his original contention.

The reason for the infarction lies in the function of the cardiac nerves removed by the operation, both sensory and motor nerves being removed. The motor nerves are coronary dilators and their removal leads to permanent vasoconstriction which is a serious element in coronary disease. Acute cardiac failure is also found more often in surgically treated patients although this condition is seen less often since all the patients with angina are no longer operated upon. A myocardial infarction in nonsurgical cases is produced so slowly that the collateral circulation has time to become established, whereas this does not occur in surgical cases. The operation of Olivecrona is compared to resection or simple removal of the stellate ganglia alone, and this is considered less objectionable for fewer accidents are said to occur. Certainly the mortality rate is much lower in atellectomy than in the more extensive removal of the upper part of the thoracic sympathetic chain. According to Danileopolu, this is a matter of statistics in which nonsurvivors are not interested. He believes that there should be a close follow up of these 71 cases, and he has little doubt that further complications will ensue. The relief of pain is not discussed.

ADRIEN VAN BAUGHEN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Present Day Criteria for the Treatment of Breast Cancer (Cr terio atual no tratamento do c ncer da mama) ANT NIO PRUDENTE. *Rev. bras. cancerol.* 1947 1: 11

In this article the author reviews the evolution of the treatment in cancer of the breast and states that it is indicative of medical and surgical progress generally. Such progress embraces not only surgery itself but likewise the fields of pathology, roentgenology and endocrinology.

Breast tumors with particular reference to malignant ones, can be grouped under the following clinical classification:

- Stage 1: Tumor confined to the breast itself
- Stage 2: Axillary involvement with movable nodes
- Stage 3: Axillary involvement with fixed nodes
- Stage 4: Supraclavicular involvement with movable nodes
- Stage 5: Breast tumor fixed to the chest wall with fixed supraclavicular nodes, cutaneous extensions or distant metastases

In brief summary lesions in stage 1, particularly those of low grade malignancy histologically, can be treated by simple mastectomy accompanied by removal of the pectoral fascia. In young women a reconstructive or cosmetic type of mastectomy seems justified.

Tumors in stage 1 or 2 with higher grades of malignancy (histologic grades 2, 3 and 4) should be subjected to radical mastectomy (Halsted).

In stages 3 and 4, that is, tumors presenting a fixed axillary mass or accompanied by movable supraclavicular nodes a more radical approach in the form of mastectomy and interscapulothoracic amputation is indicated. Supraclavicular dissection and resection of the axillary vessels as an extension of the Halsted type of operation should not be undertaken, because the result of such a limited approach in these cases is disappointing.

Electrosurgical techniques offer significant advantages provided that coagulated tissue of sufficient amount to interfere with wound healing is not produced.

R ntgen therapy is at its best when used to complement surgical treatment in the highly malignant types (histologic grade 4) of medullary carcinomas and papillary cyst adenocarcinomas. In inoperable cases it will bring about local and symptomatic improvement. Castration by x-ray treatment is indicated in far advanced cases with osseous metastases. It is simple to carry out.

Testosterone propionate used after mastectomy in stages 1 and 2 is considered to have produced better results than those obtained by mastectomy alone. Statistical references to the author's material in this

regard are given. Gratifying relief was obtained in the inoperable cases from intensive treatment with testosterone propionate.

TRACHEA, LUNGS, AND PLEURA

Bronchial Lavage (El lavado bronquial) BENJ N NOCER. *Rev. med. cir. Habana* 1947 52: 527

Even with the adjuncts of bronchoscopy and bronchography, the diagnosis of pulmonary tuberculosis in certain cases remains doubtful because of the lack of demonstration of the causal agent, the tubercle bacillus. This occurs even in patients raising sputum but in patients who have no sputum demonstration of the bacillus is more difficult, although gastric lavage is frequently employed as an aid. In an attempt to increase the number of patients in whom the tubercle bacillus can be demonstrated positively the technique of bronchial lavage has been devised. Organisms being found in material recovered from the tracheobronchial tree following induced coughing.

Abreu of Argentina first reported this work in 1944 although Castillo is said to have used the method in 1943 without publishing his results. The technique described here is essentially that of Castillo and is as follows:

With the patient supine but his head elevated the base of the tongue, uvula, and pharynx are anesthetized with a 1 per cent novocaine. A catheter is then introduced through the nose into the pharynx. The patient is placed with the suspicious side down and novocaine is then injected into the bronchial tree. After 5 minutes from 20 to 40 c.c. of sterile physiologic serum are injected via the catheter into the tracheobronchial tree. The patient is thus caused to cough and all of the expectorated material is collected. Particular attention must be paid to the amount of anesthesia produced so as not to suppress completely the cough reflex on the one hand or to affect the reflex so little that the patient gags and swallows the material instead of aspirating it. The collected material is carefully mixed with alkali and incubated 24 hours. It is then centrifuged, washed neutralized, recentrifuged, put on a slide, dried, stained, and examined for the presence of acid-fast bacilli.

The procedure appears to be indicated in patients with a suspicious pulmonary shadow but with no sputum or negative sputum in patients having positive sputum previously but which has become negative on treatment, patients who by the usual methods are said to be cured or their condition inactive, the family members of patients with positive sputa, and patients with chest lesions that are diagnostic problems. The chief contraindication is found in patients with recent hemoptysis although asthma fits in an acute crisis should not be subjected to the

procedure. No serious accidents or complications following the procedure have been reported.

The author reports 20 cases studied by bronchial lavage in which the usual methods had failed to demonstrate the tubercle bacillus. He found 19 of these to be positive on stained smears of the expectorated material, a percentage of 95 per cent. Thirteen of these had revealed no sputum and 7 had repeatedly revealed negative sputa. Five patients had had gastric washings without successful demonstration of the bacilli. Among the 20 cases all types of pulmonary tuberculous lesions were revealed by means of the lavage.

In the comparison of the positive results from bronchial lavage with those of gastric lavage a review of the reported statistics shows a range of from 0.5 to 5 per cent positives, with an average of 47.3 per cent, for bronchial lavage and a range of from 60 to 4 per cent positives with an average of 32.22 per cent for gastric lavage. The author reports 95 per cent as the highest. He considers the method an extremely important one in the questionable and difficult cases but points out that further proof by inoculation of the collected material into guinea pigs is needed to confirm the results obtained by the stained smears. (JAMES E. THOMPSON, M.D.)

Tracheobronchial Tuberculosis (Traqueo-bronchitis tuberculosa). MARCEL RODES DE DUTRA. *Rev. dermatol.* 945, 8, 24.

This article presents a review of the experience in the management of tracheobronchial tuberculosis during one year. It represents 333 bronchoscopies in 343 patients. There was no significant difference in incidence between men and women. There were only 3 patients below 20 years of age.

The incidence of tracheobronchial lesions in this group was 74 cases, the largest percentage incidence occurring in the age group over 40 years (31.7%).

Bronchoscopy was not used routinely in all tuberculous patients. The principal indications were signs of bronchial obstruction, radiologic evidence of obstruction, unexplained positive sputum, or clinical evidence of inadequate bronchial ventilation as determined by the behavior of a pneumothorax. When the indication included clinical signs of bronchial obstruction, disease was seen in 51.3 per cent of the cases examined in pneumothorax failures, in 36 per cent and in cases with unexplained or persistent positive sputum in 22.7 per cent. The contraindications to bronchoscopy were extensive laryngeal ulceration, severe hemoptysis, acute upper respiratory infections, and excessive dyspnea.

There appeared to be no correlation between the demonstration of tracheobronchial lesions and the duration of the disease although such lesions were predominant in the cavernous type of pulmonary lesion (60.8% of demonstrable tracheobronchial lesions occurred in patients with cavernous lung disease).

The author points out that in this series, mere mucous changes were not catalogued as definite lesions.

only those cases wherein the presence of a bronchial lesion was unequivocal and definite being included. He classifies them into four types: (1) infiltrative (38 cases)—hyperplastic mucosal lesions not infrequently accompanied by epithelial erosion; (2) ulcerative (21 cases); (3) ulcerogranulomatous (11 cases); and (4) fibrostenotic (4 cases).

The lesions found corresponded in localization to that of parenchymatous disease quite closely. In 4 cases the lesion involved the trachea. The upper reaches of the bronchial tree were most frequently involved and in only 1 instance was a lesion found on the side opposite the pulmonary disease.

The author emphasizes the importance of not aggravating the seriousness of demonstrable bronchial lesions in denying the patient suitable collapse therapy. The mere presence of a visible lesion without definite obstruction need not necessarily preclude the adoption of such measures. These lesions were generally treated topically with 30 per cent silver nitrate and the author claims healing in 33 per cent, improvement in 28 per cent, no change in 34 per cent, and progression of the disease in 6 per cent. Electrocoagulation has been used with success, but because of its apparent propensity to produce heavy scars, stenosis may result. Promin given locally is ineffective. Ultraviolet light and radiation therapy were not used. Streptomycin has been used and dramatic results are cited, but its scarcity has precluded any adequate trial. The author reviews the argument against the effective use of local treatment but believes it to be valuable even if not the entire answer to the problem. (HIRSH T. LANGSTON, M.D.)

Wet Lung—An Experimental Study. ROLLA A. DAMEL, JR., and WILLIAM R. CATE, JR. *Ann. Surg.* 945, 7, 836.

A series of carefully controlled experiments produced traumatic wet lung in mongrel dogs by both blunt trauma and tangential bullet wounds of the thoracic cage. The term "wet lung" denotes the accumulation of fluid in the lungs following accidental or operative trauma. The fluid consists of blood transudates, exudates, or mucous in any combination. The phrase pulmonary edema which in its strict sense implies an increase in interstitial fluid, often is loosely applied to the condition known as wet lung.

The pathologic picture is one of extravasation of blood in the lung and the transudation of fluid into the interstitial spaces as well as the alveoli and bronchi. The amount of fluid produced in each experiment varied directly with the degree of trauma. The pulmonary fluid appeared rapidly after thoracic trauma. It was still present in proportion to the trauma inflicted, at 24 hours and had largely disappeared at 72 hours. Even in those areas of the lung exhibiting no gross evidence of trauma, fluid could be demonstrated, frequently in considerable amounts. However, the greatest degree of pulmonary wetness was found in the areas of greatest hemorrhage in the traumatized lung.

Intravenous infusions of isotonic sodium chloride in amounts and at rates of injection which have little effect on normal animals intensified the wetness of a slightly traumatized lung. Generalized pulmonary edema resulted. The authors believe that anoxia per se does not explain the wetness in grossly untraumatized areas of the lung following thoracic injuries.

Studies of the arterial oxygen saturations, hematocrits, peripheral venous pressures, peripheral arterial blood pressures and the pulse rates in the experiments did not reveal variations of enough significance to explain the occurrence of generalized wet lung associated with localized areas of pulmonary injury.

In an effort to explain the occurrence of fluid in the nontraumatized areas of the lung, experiments were performed which indicated that generalized wetness following local trauma to the thoracic cage and the lung is in part a reflex neurogenic phenomenon.

ORVILLE F. GRIMES, M.D.

Pneumoconiosis Due to Talc in the Cosmetic Industry NATHAN MILLMAN *Occup Med* 1947 4:391

The report of a case of pneumoconiosis due to talc is presented. The author emphasizes the fact that contrary to prevailing beliefs, prolonged exposure to talc in sufficient concentration is capable of producing generalized pneumoconiosis of the nodular type. The elements of silica and asbestos were eliminated as a cause of the pneumoconiosis in this particular patient since there had been no exposure to these substances in any industry prior to his exposure to talc in the cosmetic industry. Also, the chemical analysis of the talcum powder revealed less than 0.5 per cent free silica.

ORVILLE F. GRIMES, M.D.

Situs Inversus, Bronchiectasis, and Sinusitis—the Kartagener Syndrome. Report of 2 cases. (Transposición de vísceras—bronquiectasia y sinusitis Síndrome de Kartagener) JUAN MARTÍN ALLENDE and LÁZARO LANGER. *Cirugía* 1947 1:176.

The association of bronchiectasis and true dextrocardia was first described in 1904 by Siewert, but few references to this condition appeared in the literature until Kartagener described the triad which bears his name in 1933, consisting of situs inversus, bronchiectasis and paranasal sinusitis. He reported 4 cases at that time, later collecting 7 more.

The literature on this subject, as well as that relating to the association of upper and lower respiratory tract disease is briefly reviewed. The etiology of bronchiectasis cannot be given any more certainly under these circumstances than in its uncomplicated status, but it does seem that in persons with situs inversus, bronchiectasis may well appear more frequently.

The first of the authors' cases was a young man age 17 with a long history suggestive of bronchiectasis. He had a transposition of thoracic as well as abdominal viscera, and clinical as well as roentgen

ographic evidence of maxillary sinusitis. Bronchography revealed a lower lobe bronchiectasis in the right chest, which contained in anatomical pattern a left lung. Lower lobe lobectomy was performed with relief of the symptoms.

The second case was that of a girl 14 years of age. Birth was complicated by atelectasis of the left lung. She presented a complete transposition of the viscera and clinical as well as roentgenographic evidence of maxillary sinusitis. Bronchography revealed bronchiectasis in the left chest, involving the middle lobe of what was in anatomical pattern a right lung. A successful lobectomy of the middle lobe was performed.

These patients were treated in 1946 and 1947 respectively.

Twelve references to the literature are given.

HIRSH T. LAROSTON, M.D.

Cancer of the Lung in the Female (Cáncer del pulmón en la mujer) ANDRÉS A. SANTAS *Bol Inst* 1947 33:134.

It has long been known that pulmonary cancer is much more frequent in men than in women. Various authors report the incidence in women to be between 12 and 20 per cent except in Argentina where the figures are lower, ranging from 2.5 to 11 per cent. The author reviewed the 350 cases examined in the Institute of Clinical Surgery in Buenos Aires between 1933 and 1941 and found only 7 females, an incidence of 2 per cent.

The cause of the greater incidence of pulmonary cancer in men is unknown. The part played by tobacco and industrial occupations has long been discussed but with the increased use by women of tobacco and the widespread employment during the war of women in factory jobs formerly occupied by men, there has been no reported equality or even increase in the relative incidence of pulmonary cancer in the female. In general, one must look to the fundamental biological differences in the two sexes as manifested in their specific hormonal secretions to account for the difference but just how this comes about is unknown.

Bronchogenic carcinoma in the female has the same histologic characteristics as in the male. Epithelioid carcinomas, adenocarcinomas and undifferentiated epitheliomas are recognized. There is disagreement in the literature in regard to the so-called endothelioma. Some authors consider it of vascular or pleural origin while others consider it a bronchogenic epithelial tumor. Such a tumor differs from the usual carcinoma, however, in that it is more frequent in the female, grows slowly, rarely metastasizes, gives a rounded homogeneous shadow by x-ray and is of low malignancy. One of the cases in the author's series was classified as hemangioendothelioma. Bronchial adenomas also appear to be more frequent in the female than in the male. A point of interest is that epidermoid carcinomas are relatively infrequent in the female, the adenocarcinomas being the predominant type. This fact cannot account for

the overall difference in incidence of pulmonary cancer in the female, however.

The author reports 7 cases of female patients with malignant pulmonary tumors among a total of 350 cases reviewed. In these neither tobacco nor industrial occupations were factors of significance. All of the women performed domestic duties. None suffered from any other chronic pulmonary disease. Five were from urban areas and 2 from semirural areas. Histologic proofs of the diagnosis were obtained in 6 cases, 3 by bronchoscopy, 2 by thoracotomy, and 1 by node biopsy. It was not possible to classify the type of tumor in 1 of these 6 cases. Of the remaining 5, 2 were adenocarcinomas, 1 was epidermoid carcinoma, 1 undifferentiated epithelioma, and 1 hemangioendothelioma.

Among the total cases in the women patients epidermoid carcinoma was found in 1.17 per cent, adenocarcinoma in 3.63 per cent, undifferentiated tumors in 6.25 per cent, and hemangioendothelioma in 100 per cent. Among the 5 cases, adenocarcinomas represented 40 per cent, however, the series is too small to warrant any final conclusions.

JAMES F. THORNTON, M.D.

Carcinoma of the Lung. Factors Affecting Survival after Resection of Cancer of the Lung. RALPH ADAMS. *J. Thorac. Surg.*, 1948, 17: 306.

During the 15 year period ending December 1945 the diagnosis of lung cancer was microscopically established in 183 patients at the Lahey Clinic, Boston. Fifty six, or 30.8 per cent of these were resectable. Of the 56, 8 or 14.3 per cent died in the hospital. This hospital mortality has now been reduced to 5.1 per cent during the past 5 year period.

Analysis of factors involving the survival of the remaining 48 patients shows the following:

Duration of symptoms. Approximately 60 per cent of all patients survived one year following operation regardless of the duration of the preoperative symptoms. Thereafter the rate of death with epidermoid cancer is directly related to the preoperative duration of symptoms. In cancers of other types the cell type is more important than the duration of symptoms.

Site of lesion. This does not affect the survival rate.

Type of operation. Thirty five of the 48 patients were resected by pneumonectomy and 13 by lobectomy. The survival rate was equally good for each type of operation but it should be remembered that patients with the more advanced lesions were treated by pneumonectomy.

Survival with respect to nodal involvement. The regional lymph nodes were involved in 18 of the 48 patients and not involved in 30. The absence of demonstrably involved nodes increases the patient's chance of being alive and well 5 years after the resection, three fold.

P. signs in relation to cell type. This is the most important singular consideration in the estimation of the prognosis after resection. In undifferentiated

cancers less than a year of life may be expected. Patients with epidermoid carcinoma have the best prognosis of long survival. The longest survival with adenocarcinoma has been 5 years. Broder's classification of the epidermoid carcinoma is confirmed as a prognostic aid in this group.

FRANK B. QUEEN, M.D.

ESOPHAGUS AND MEDIASTINUM

On the Pathogenesis and Surgical Treatment of Esophageal Diverticula. (Sobre la patogenia y tratamiento quirúrgico de los divertículos del esófago) L. PERA LOPEZ. *Rev. esp. pat. cir.* 1946, 4: 333.

Modern x ray examination has been the main factor responsible for the increased frequency of recognition of esophageal diverticula, and has made possible a definite diagnosis of certain symptom-pictures heretofore undiagnosed.

Diverticula of the thoracic esophagus apart from those due to traction from scarring arising in the hilar glands are congenital in origin. When symptoms are severe enough to warrant surgery, they can be treated by inversion of the sac into the esophageal lumen by excision of the sac and layer closure of the esophageal wall, or by Lahey's method of tacking the dome of the diverticulum superiorly to the side of the vertebral bodies which allows it to collapse and prevents food from entering it. These diverticula are quite uncommon as compared with those of the cervical type.

The pharyngo-esophageal diverticula are those most frequently encountered. The pathogenesis of these lesions is still disputed. They arise in the weak triangular area of the pharyngo-esophageal junction. Many authors consider congenital defects or alterations in the musculature in this area as the basic cause of the formation of diverticula. Others have called attention to the inco-ordination or spasm of the cricopharyngeus muscle during deglutition, with continued intermittent pressure on the weak esophageal wall as a factor. Probably all these factors contribute and over a long period of time the diverticula enlarge and begin to give their characteristic symptoms, consisting of regurgitation, dysphagia, bad breath, and, in later stages, compression of nearby structures—the recurrent nerve, sympathetic trunk, and trachea. Pathologically these diverticula show inflammation, with the formation of polyps and papillary projections, ulcerations which may perforate and malignant degeneration.

Lahey has divided these lesions into three stages: (1) that producing no symptoms, (2) that in which there are symptoms without obstruction and (3) that with symptoms and esophageal obstruction. Ideally they should be operated on in stage 1 and those in the asymptomatic stage should probably not be operated upon.

The early surgical treatment consisted of a one stage excision of the sac but because of high mortality from infection a two-stage procedure was gradually evolved. This two-stage operation has been

championed by Lahey. In the first stage the sac is freed elevated with its dome superiorly, and externalized to allow for adhesions to seal off the mediastinum and fascial planes of the neck. At the second stage the sac is amputated and the stump either closed primarily or packed with a small piece of gauze and allowed to heal.

In recent years with the protection of chemotherapy and antibiotics the tendency has been toward a one-stage operation in which the sac is very carefully freed and amputated under strictest aseptic precautions, then a layer by-layer closure of the esophageal wall is done. The results of this method appear to be just as satisfactory as those of the two-stage method and the second operative procedure is obviated. Under certain circumstances arising at the time of operation, the two-stage maneuver may appear preferable. The author describes in detail the case of a large diverticulum treated successfully in two stages.

JESSE E. THOMSON, M.D.

The Treatment of Carcinoma of the Esophagus and Cardiac End of the Stomach by Surgical Extirpation RICHARD H. SWEET *Surgery* 1948, 43: 952

Because of the anatomic and physiologic aspects of the esophagus surgery of this organ demands separate consideration, according to the various levels at which carcinoma occurs (Fig. 1). Surgery for carcinoma of the cervical segment of the esophagus utilizes a skin flap transplant. The operation is almost perfect from a standpoint of restoration of function, but is a failure as a measure of cure. Recurrence is inevitable, and prolongation of life cannot be insured.

Carcinoma of the thoracic segment involving the upper fourth of this region requires a thoracotomy incision through which the entire esophagus from the base of the neck to the cardia is dissected free and the stomach is completely mobilized. An esophagogastric anastomosis is performed within the neck, above the level of the clavicle. Although the operation has limitations, it is the most effective palliative method thus far devised.

Surgery for carcinoma of the middle half of the esophagus includes lesions superior to the aortic arch and those inferior down to the level of the inferior pulmonary vein. A high esophagogastric anastomosis is employed in the reconstruction whereas a low esophagogastric anastomosis is used in resection of carcinoma involving the lower fourth of the thoracic esophagus.

After infection is eliminated the most important immediate postoperative complications are cardiac arrhythmias and congestive failure. Antibiotics have materially reduced the occurrence of infection. An intranasal catheter for the administration of oxygen has been most efficient. Continuous Levine suction of the stomach, aspiration of the thoracic cavity and early ambulation have contributed to reduced mortality.

Radical resection for carcinoma of the esophagus offers the patient a survival in relative comfort with-

Fig. 1 (Sweet) Anatomic regions of the esophagus and cardiac end of the stomach illustrated to facilitate the understanding of the technical problems involved in the surgical management of carcinoma arising at various levels.

out dysphagia. Appraisal of the operation as a curative measure awaits the accumulation of cases showing the accepted 3 to 5 year survival time. As a palliative measure the operative approach has a positive value as demonstrated by the 303 resections reported.

STEPHEN A. ZITMAN, M.D.

Cancer of the Cervical Esophagus. WILLIAM L. WATSON and JOHN L. POOL, *Surgery* 1948 43: 893

The clinical material for this report consists of a consecutive series of 77 patients with cancer of the cervical esophagus admitted to Memorial Hospital New York, in the 7 year period from 1940 to 1947.

The results of treatment for cancer of the cervical esophagus have been discouraging up to the present time for a variety of reasons. Dysphagia, the most prominent symptom of esophageal cancer at any level, is usually a late symptom, because it does not manifest itself until there is fixation of a large enough portion of the pliable esophageal wall to cause sufficient blockage of the gullet to interfere with the passage of food. The esophagus does not contain pain fibers and therefore, symptoms are necessarily due to pressure on adjacent organs and structures. Early in the disease a feeling of roughness in the throat, halitosis, or slight vague and ill localized discomfort on swallowing occurs. The patient is

likely to shrug off these premonitory symptoms. When the disease is finally diagnosed the patient may be shuttled between the nose and throat specialist, the general surgeon, and the x-ray therapist unless he falls or is steered into the hands of a physician particularly interested in this disease and capable of treating it.

The lesion under discussion occurs in the upper 30 cm. of the esophagus, thus including a portion of the gullet which extends into the thoracic inlet. (lobus hysterica and thyroid disease are the two most frequent diagnostic errors encountered. The esophagus should be studied carefully under the fluoroscope not only with a thick barium suspension in order to outline the gullet, but also to assess the mucosal pattern after the bolus has passed. Esophagoscopy should be carried out in every suitable case as the next diagnostic measure. When leucoplakia is present in the mouth, an investigation of the esophagus is not amiss, as there is a definite association of precancerous leucoplakia in the whole of the upper digestive tract. The Plummer Vinson syndrome and carcinoma may be difficult to differentiate and it is possible for the two diseases to coexist. In the series of 13 women, 3 had sufficient evidence to warrant the diagnosis of Plummer Vinson syndrome. Other factors which may cause a disorder in the swallowing mechanism and which must be ruled out are prominent osteoarthritic spurs of the lower cervical vertebrae in the elderly, a retropharyngeal abscess, tuberculosis of the cervical vertebrae, recurrent laryngeal nerve paralysis, and thyroid or lymph node enlargements.

If a patient with carcinoma of the cervical esophagus is put on a high caloric, supportive liquid diet the life expectancy is approximately 3 months. A satisfactory gastrostomy increases life expectancy slightly. In two-thirds of the cases, x-ray therapy brings about some degree of amelioration of the symptoms and at least all the saliva to be swallowed. The life expectancy of a patient after x-ray therapy and gastrostomy is more than a year and an occasional patient may have complete arrest of the cancer.

There are three established methods of surgical attack on this problem of cancer of the cervical esophagus.

The Torek procedure is indicated in the high intrathoracic lesions, or those at the thoracic inlet. The cervical esophagus is brought out through the neck wound the tumor excised and the margin of the proximal esophagus sutured to the skin at a suitable level. A skin-lined anterior chest wall esophagus can be constructed later.

The radical operation for cancer of the cervical esophagus which invades the posterior region, the arytenoids, the thyroid gland or trachea itself and was described by Trotter, Eggers, and Woolsey each independently. It consists in resection of the larynx, esophagus, and the adjacent jugular lymph nodes en bloc. A preliminary gastrostomy is made, and a low tracheostomy is provided under local anesthesia to furnish an airway and an opportunity to introduce

oxygen. At a later stage, the cervical esophagus is reconstructed by a skin lined tube turned in upon itself and sutured to the two ends of the esophagus.

3 Segmental resection a less radical resection, of the cervical esophagus is feasible when cancer has not extended completely through the muscular coat. This holds true even for those lesions at the cricopharyngeal pinchcock where the tumor is partially on the anterior wall. In such cases resectability without sacrifice of the larynx cannot be determined until exploration of the posterior space is undertaken. Lesions as low as the sternal notch can be resected in this manner. Preliminary gastrostomy may be indicated, and tracheostomy is essential.

Two methods are available for completion of the operation. If the lesion is particularly ulcerated and infected the esophagus may be exteriorized by suturing a Padgett graft behind it. From 4 to 7 days later the involved segment of the esophagus is resected. The authors prefer to resect the esophagus at this stage and suture the superior and inferior stoma to the replaced skin flap margins. A graft is often needed over the prelaryngeal muscles, and later tubular reconstruction.

In this series there were 11 operations on the cervical esophagus in 27 cases, an operability rate of 4 per cent. In 7 cases (64 per cent) the tumor was resectable. Of the 7 patients resected one died on the second postoperative day of pulmonary edema and myocardial infarction. The immediate covalence of the other 6 patients was uncomplicated. Four patients were alive and well 7 years, 1 year 9 months and 6 months, respectively after resection without recurrence. Two were alive with recurrence 3 years and 3 months, respectively following surgery.

Cancer of the cervical esophagus, if discovered reasonably early in its course can be cured surgically and even when the disease is advanced and cervical metastases are present, a control of growth may be obtained by aggressive surgery plus substantial irradiation.

HAROLD LAUFMAN M.D.

Seven Resections of the Thoracic Esophagus for Carcinoma, with Esophagogastric Anastomosis, followed by Operative Cure (A propos de sept resections de l'oesophage thoracique pour cancer avec anastomose oesophago-gastrique, suivies de guérison opératoire). ALAIN MOCHEUX and P. VI ONSOX. Mém. Acad. chir., Par. 918, 74-85.

During a period of 3 months, the authors saw 13 cases of malignancy of the thoracic esophagus. Four of the patients were inoperable, but 9, between the ages of 33 and 68 were operated on. Two of the latter died of shock and pulmonary edema, 7 presented an operative cure.

According to the site of the tumor two different methods of operation were used. In the low tumors (4 cases) the left transpleural approach with resection of the eighth rib and section of the neck of the sixth and seventh ribs was used. The stomach was mobilized as far as possible toward the pylorus by severing the gastocolic ligament. The coronary

artery was ligated in order to remove the lymph nodes at the small curvature. The esophagogastric anastomosis was performed at the anterior aspect of the stomach.

In the high tumors (middle esophagus 5 cases) the technique of Garlock and Sweet was employed. This consisted of supraumbilical incision, liberation of the stomach and ligation of the small vessels of the mesoesophagus at the level of the hiatus. Then the abdominal incision was closed, the patient turned on his left side, a right thoracotomy was done parallel to the sixth rib and the tumor was dissected.

WERNER M. SOLMITZ, M.D.

Surgery of the Thoracic Esophagus (Sur la chirurgie de l'oesophage thoracique) F. D. ALLAINES and CH. DUBOST. *Bleu Acad. chir.*, Par. 1948 74 151.

Malignancies of the thoracic portion of the esophagus offer a poor prognosis in most cases because of early metastases in the mediastinal lymph nodes and invasion of the neighboring organs and because of the poor general condition of the patient at the time a correct diagnosis is made.

At the convention of surgeons in Paris 1947, the authors gave a report of 65 cases of their own observation. Fifteen of their patients were operated on and only 1 of these 15 was alive and well 8 months after the operation. Since last year however improvement of anesthesia equipment and shock treatment have made the prospect less gloomy. Four cases in which operation was done since October 1947 are described in detail. All of the patients survived.

If curative resection is impossible because of invasion of the lymph nodes and adjacent organs palliative resection is preferable to gastrostomy. Although the patient cannot be saved in the long run he can lead a comfortable life for some time and will not be subjected to the miseries of gastrostomy. The technique of palliative anastomosis between the esophagus and stomach without resection is described in detail, and six cases in which operation was done by this method are reported.

WERNER M. SOLMITZ, M.D.

Acute Posterior Mediastinitis from Per-Oral Wounds of the Esophagus (Les médiastinites aiguës postérieures par plaies endo-œsophagiennes) RAOUL JOUSSEMET. *J. chir. Par.*, 1948 64 180.

The author presents a 10 year study of acute posterior mediastinitis resulting from wounds of the esophagus via the per-oral route. Esophageal perforations were shown to occur as frequently from instrumental maneuvers as from the ingestion of foreign bodies. The esophageal wall, composed of only mucous and muscular coats without a serosal layer is particularly vulnerable to traumatism. Perforations are most common in the cervical esophagus.

The anatomical arrangement of the several fascial planes leading into and away from the posterior mediastinum favors propagation of the infection with but little tendency toward localization. Likewise the negative pressure within the thorax, the constant motion of the mediastinal structures from movements of deglutition of the esophagus and the addition of infective agents from the saliva from repeated swallowing efforts tend to cause progression of the infective process. The abundant lymphatic supply of the posterior mediastinum is also a factor in the spread of infection introduced into the posterior mediastinum by endoesophageal wounds.

Two factors are important in the recognition and management of esophageal perforations incurred through the per-oral route.

1. The wound in the esophageal wall permits the entry of air into the periesophageal tissues which infiltrates along the fascial planes and along the great vessels. The presence of air is an important roentgen sign in establishing the diagnosis of an esophageal perforation.

2. The anaerobic nature of the organisms from their natural habitat in the mouth and pharynx makes for an especially virulent symbiotic bacterial relationship.

The immediate surgical repair of esophageal wounds through an adequate approach either cervical or high thoracic is advocated by the author and is substantiated by favorable statistics.

ORVILLE F. GARDNER, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Chronic Eventrations and Voluminous Herniations.
Preparation by Progressive Pneumoperitoneum.
(Eventraciones crónicas y hernias voluminosas. Preparación con el neumoperitoneo progresivo. Procedimiento original) IVÁN GÓMEZ MORAÑO. *Cirugía*, 947 59.

Since 1940 approximately 80 cases of large hernias and eventrations have been prepared preoperatively by progressive pneumoperitoneum. Patients with umbilical hernias, relatively small foramina and flaccid ventral walls do not require preparation with pneumoperitoneum. However the procedure gives its maximum benefit to those patients with large rings tense abdominal walls, and above all those with postoperative eventrations.

The procedure as described has two principal actions: first, it reduces the disproportion between the abdominal cavity and its contents; second it alleviates the respiratory changes attendant upon a rapid postoperative rise in intra-abdominal pressure.

Intra-peritoneal insufflations of air reproduce in miniature the postoperative picture. At first there is an increase in the intra-abdominal pressure elevation of the diaphragm and labored respiration. For this reason the first administration of air necessitates prudence. The second and third "pneumums" are all ways well tolerated and the quantity of air may be markedly increased. Another significant fact is that the vital capacity is not diminished at the end of 2 or 3 weeks even though the abdomen is under extreme tension.

In 2 or 3 weeks after four or five administrations of progressively increasing amounts of air up to 6 or 8 liters, the patient has no more than slight discomfort, while if the same patient had received from 500 to 1,000 c.c. of air at the first treatment, he would have had reactions of abdominal tension, dyspnea, and pain in the left shoulder. The vital capacity of the same patient, which was 1,500 c.c.m. before the initiation of treatment, dropped to 1,000 c.c.m. after the first treatment; then it was augmented and established at between 1,500 and 2,000 c.c.m. during the last treatment.

Upon opening of the abdomen under local anesthesia, the air is expelled and the patient experiences relief; the abdominal muscles are loose and the viscera do not protrude. Ordinarily spinal or general anesthesia are preferred.

The primary effect of the pneumoperitoneum is to reduce the edema of the peritoneal membranes, omenta, and adipose tissues, to exert pressure on the large dilated veins and as a consequence improve the venous circulation of the lower extremities; reduce distention of the viscera, elongate adhesions and weaken the muscular tension so that tissues may be approximated without strain when sutured.

Secondarily as a result of the elevated intra-abdominal pressure due to pneumoperitoneum there is strengthening of the diaphragm as well as of the other muscles of respiration, stabilization of the vital capacity during treatment, increase of the vital capacity after operation, and improvement of the venous return as a result of the improved thoracic respiration.

The procedure should not be used in patients of advanced age, in debilitated patients, in decompensated cardiopathies or in strangulated hernias of many hours duration. Notwithstanding, the procedure may be used in 90 per cent of the general cases of eventrations.

Besides the immediate advantages of the method, it provides an excellent test of tolerance for the operation. A patient who would be incapable of tolerating even carefully graded doses of air in the abdominal cavity would not be a suitable candidate for the operative procedure. HAROLD W. BENDIS, M.D.

Mesenteric Thrombosis. J. E. MCCLENNAN and BENJAMIN FISHER. *Surgery* 64:3, 3 773.

In November 1944 Ficarra reported 569 cases of mesenteric thrombosis with 35 successful resections. Since then no large series has been reported. A review of the literature since Ficarra's article adds 7 more cases with 3 successful resections. To these are now added 40 cases with 5 successful resections, bringing the total to 616 cases with 43 (7 per cent) successful resections. Since there was an average of 10,000 admissions per year at the Mercy Hospital, Pittsburgh it was found that the incidence was 1 case in 5,000 or 0.2 per cent.

Of the 40 patients, 23 were men and 17 were women. All 40 were white persons, no negro receiving the diagnosis in spite of the fact that many were admitted. In comparing the incidence with other places it was found that the Michael Reese Hospital in Chicago had 41 cases in 10 years. The Kings County Hospital in New York had 35 cases in 8 years.

Although the incidence of mesenteric thrombosis is greatest between the third and sixth decades, this condition may occur at any age. In one series the youngest patient was 27 years old and the oldest 81. Of these cases 57 per cent occurred between the ages of 40 and 60 years.

In a series of 40 cases, the diagnosis was definitely proved in 27 or 67 per cent by either operation or autopsy. Of these 27 cases, 11 came to autopsy, 16 of the patients were operated upon and 3 of these came to autopsy after operation. The remaining 13 cases, or one-third of the total, were diagnosed clinically and, of course it was quite impossible to prove the diagnosis in that group.

The 3 cases of the condition not proved by operation or autopsy could be dismissed by saying that of this number 12 patients died, a mor-

tality of 98 per cent. Of these 13 cases, 8 were the result of primary heart disease 3 followed previous surgery, and 2 were primary in nature. Operation was not attempted in any of these cases because of the generally universal feeling by the surgeon that the patient could not tolerate surgery.

In the proved group of 17 cases, 19 patients were operated upon and 5 lived, a mortality rate of 73 per cent. In this group of 19 there were 6 in whom nothing but the diagnosis was established by opening and closing the abdomen. One cannot consider these individuals as having been operated upon in the ordinary conception of surgery. All 6 died. Of the remaining 13 upon whom some operative procedure was done, 5 or 39 per cent, lived. For all the cases in which some operative procedure other than just opening and closing the abdomen was performed the mortality rate was 61 per cent. For the group in which nothing was done, the mortality rate was 95 per cent. Thus, it would seem that surgery gives the patient about one chance in three to survive while watchful waiting has little to offer but death.

Radical surgery that is wide resection and anastomosis, is the only tenable treatment in those cases in which there is extensive gangrene of the bowel.

The condition may often present itself in a mild form not always as the severe accident as is so commonly believed.

The mortality rate of the patients in the Mercy Hospital was 61 per cent for those operated upon and 95 per cent for the remainder. The total mortality rate was 85 per cent for 40 cases.

A brief discussion of the anatomy and pathologic physiology was presented with emphasis on the col lateral circulation.

An outline of etiologic factors was presented and arterial thrombosis of arteriosclerotic origin was the most common cause of the condition in the series.

The presentation of 2 cases demonstrated the clinical picture of this condition. The signs and symptoms are not consistent.

It is believed that the use of heparin and dicumarol must be considered. They may possibly be of great value postoperatively.

HARRY W. FOX, M.D.

GASTROINTESTINAL TRACT

Cardioesophageal Cancers Treated via the Trans-thoracic and Transdiaphragmatic Route. FELIX DE AUSTRI and ELISEO QUINTANA. *Surgery* 1948 23 921

In 39 patients with cardioesophageal cancer who were treated by the authors between September 1943 and September 1946 it was possible to perform radical operation in 14 (36 per cent). All of the lesions of the distal third of the esophagus or cardioesophagus were explored through the thorax by resection of the ninth rib and incision in the diaphragm. Nonresectable lesions were (1) those tumors which at exploration of the thorax were accompanied by hemorrhage freely collected in the pleural cavity, neoplastic nodules disseminated in the pleura, (2)

adhesions en bloc with the diaphragm indicating an immovable tumor and very extensive infiltration, extensive invasion of the neighboring organs such as the aorta, bronchus, spinal column and (3) those which after incision of the diaphragm, were shown to be accompanied by liver metastases, implants in the adjacent peritoneum or the pouch of Douglas and extensive infiltration of the omentum or other intra-abdominal organs.

The anesthetic was cyclopropane in each case and was administered by tracheal intubation.

Following 14 radical resections there were 6 survivals (43 per cent of the resections or 15 per cent of the total). The average survival time was 13 months among these patients.

The cause of death in those who underwent resection and died during the first 30 days after operation was acute pleuropulmonary infection (in 6 patients). In all autopsy revealed partial separation of the sutures of the anastomotic stoma. One patient died from operative shock and another of generalized peritonitis also due to separation of the sutures.

Commenting on their experiences the authors emphasize the low resectability rate, the route of primary exploration, the determination of macroscopic evidence of delimitation of the tumor and the fact that the suture line in the anastomosis is apt to disrupt. For the latter it is suggested that fine silk Halsted sutures be employed in the posterior part joining the gastric seromuscular layers with the esophageal muscularis layer. A continuous chromic catgut suture on an atraumatic needle is used by these authors to include all the gastric and esophageal layers in the posterior part. The same method is then used in the anterior circumference. Fine silk Lembert sutures are used for reinforcement in the entire circumference. The stomach should be fixed in the thorax at the edge of the diaphragm. A Levine tube, passed above the anastomosis, was used for 5 or 6 days. Tension should be avoided on the anastomotic line.

HAROLD LAUFMAN, M.D.

The Roentgen Diagnosis of Cancer of the Cardiac Region of the Stomach. ROBERT S. SHERMAN. *Surgery* 1948, 23 874

Since gross pathology is the foundation for reliable x-ray diagnosis in gastric cancer, a classification based upon morphology is used. Three types of carcinoma are recognized: polypoid infiltrating and ulcerating. While most carcinomas contain more than one of these features, one usually predominates and permits classification. The diagnosis of an organic lesion roentgenologically is generally less reliable than its detection.

It is occasionally a problem whether a malignant tumor is of lower esophageal or of upper stomach origin. Mere identification of the bulk of the cancer above the diaphragm does not assure that it is esophageal, since intrathoracic gastric cancer is not uncommon. In the experience of the author most cancers involving the lower esophagus are found to

be of stomach origin. The various forms and degrees of herniation of stomach through the diaphragm may provide a stumbling block to the diagnosis of cancer of the cardiac region. One must exclude the possibility of intrathoracic gastric cancer in all hernia cases. In the obstructive lesions occurring at the lower esophageal orifice it is important to get enough barium into the stomach to be able to rule out gastric cancer. To accomplish this, the period of the examination may have to be considerably extended. If an air bubble is present, a careful study of its contour may provide essential information.

In a group of 205 resected carcinomas of the stomach at Memorial Hospital, New York, it was found that 2 per cent were located in the cardiac region. The author discusses the diagnostic details under the following headings: (1) mucosal alteration, (2) infiltrate (3) mass (4) ulcer (5) esophageal involvement and (6) miscellaneous findings such as obstruction, gross contour changes, general widening between the fundus and the dome of the diaphragm, lateral displacement of the stomach at the cardia, and (7) phragmatic alteration.

In checking the pathologic specimens with the roentgen diagnosis it was found that the judgment of the roentgenologist as to tumor size was about 50 per cent dependable. As for location, all ulcers involved the cardia to some extent and most of them had the cardia as their principal site.

It is emphasized that postoperative roentgenography should be used in the detection of recurrence.

HAROLD LATTMAN, M.D.

Surgical Treatment of Cancers of the Gastric Cardia GRO. T. PACE and GORDON MCNEELY *Surgery* 94:5, 3, 976.

This article is a summary of gastric cardiac surgery carcinomas as done in the Memorial Hospital, New York, New York. One hundred and twenty-two cases are listed, including 65 cases of the author.

The procedure followed is given in detail from the first presentation of the patient for diagnosis to the postoperative follow-up. The anesthetics of choice are cyclopropan, either with nitrous-oxide-oxygen and ethylene. The abdominal approach was employed in 10 patients; the transthoracic in 45; the abdominothoracic in 6; and the transthoracic with total resection in 4.

The end-results were admittedly discouraging. Twenty-one patients succumbed as a direct result of the operation. Twenty-one others died from the continuance of the growth and metastases of the cancer. Of the remainder of the patients who are living 18 are with no evidence of recurrence.

STEPHEN A. ZIMAN, M.D.

Transthoracic Gastric Resection for Lesions of the Cardia of the Stomach and Lower Part of the Esophagus. JOHN H. PAXON and Q. THOROW CLARKE *Surgery* 94:5, 3, 9.

The authors present a review of the cases in which transthoracic gastric resection was performed at the

Mayo Clinic, Rochester, Minnesota, for lesions of the cardia of the stomach and the lower part of the esophagus.

According to the authors this operation offers the best method of surgical management of malignant lesions of the lower part of the esophagus and the cardia and upper part of the fundus of the stomach.

Simple transthoracic exploration performed by the authors has not resulted in any deaths. Their immediate postoperative mortality rate for the cases in which resection was performed was 13 per cent.

Although the numbers are small, calculation by the actuarial method of Berkson indicates the following survival rates: 71 per cent of the patients lived for 1 year; 40 per cent lived for 2 years; and 31 per cent lived for 3 years.

Perforated Gastric and Duodenal Ulcers. Statistics on 95 Observations (Úlceras gástricas y duodenales perforadas. Estadística sobre 95 observaciones) P. LAROMERO YBARRI, L. M. BOER, DEL MARCO, L. MIEROLA, and F. GUTIERA. *Arch. surg. med.* 94:7, 31, 64.

Larghero *et al.* in a series of 95 cases of perforated gastric and duodenal ulcer studied in Uruguay found a gross mortality of 30 per cent. The cases are divided into three groups. In the first group were 39 cases observed from 1930 to 1940 with a mortality of 29 per cent. In the second were 29 cases followed from 1940 to 1944 with a mortality of 6.8 per cent, and in the last there were 24 cases followed from 1944 to 1946 with a mortality of 24 per cent. The authors found that the prognosis of these perforated cases depended on the time lost before the repair of the perforation was made. The prognosis is considerably more severe in cases with a perforation of longer than 15 hours' duration.

In the diagnosis of the perforations the authors found that pneumoperitoneum was present in all 6 cases of perforated gastric ulcer in which roentgenograms of the abdomen had been taken, but it was evident in only 10 of 30 cases of duodenal ulcer. In the group of cases without roentgenologic evidence of pneumoperitoneum, the perforation occurred in less than 4.5 hours in 7; in 7 hours in 1 case; in 7.5 hours in another; and in 17 hours in the last case.

The type of surgery used was as follows: suture of the perforation in 43 cases with 11 deaths; suture and gastroenterostomy in 31 cases with 5 deaths; and gastrectomy in 7 cases with 1 death.

The authors also discuss the importance of the different types of anesthesia and the type of drainage as important surgical factors in decreasing the mortality of patients with perforated ulcers.

WILLIAM L. RICKETTS, M.D.

Pathologic Perforation of the Ileocecal Colon (Perforación patológica del colon ileo cecal) JORJO V. URBURU *Cólica*, 1947, 73.

Urburu discusses perforation of the ileocecal colon in pathological conditions. The author analyzed the history, pathological anatomy, etiology

pathogenesis anatomopathology symptoms diagnosis and surgical indications of these perforations of the ileosigmoid colon

According to the author the principles fundamental in the treatment of these types of perforations are suture of the communication between the perforated intestine and the free peritoneum drainage of the intestine and the peritoneum and the anti-infectious treatment with sulfa drugs and penicillin. Of 4 patients treated by the author 3 survived. Two of them had free perforations in the peritoneum and 1 had a 'blocked' perforation in the fourth perforation was considered "imminent"

WILLIAM E. RICKETTS, M.D.

Tuberculosis of the Appendix (La tubercolosi dell'appendice) PASQUALE FIGARA and UGO PAOLIAN. TORINO. *Ann. Ist. Osp. Aquilani* 1946-47 1: 277

The authors analyze 238 appendectomies performed at the Civil Hospital in Aquila, Italy. Of these 200 represented patients operated upon for appendicitis (without perforation) and upon whom bacteriological, cultural and histological studies for tuberculosis were made and all were found to be positive in 2 cases. One of the latter showed calcified nodules pinhead in size on the cecum while the other showed no evidence of tuberculosis. Hence the authors concluded that primary tuberculosis of the appendix could be ascribed to only 1 case representing 0.5 per cent.

The other 38 cases represented those in which there was macroscopic evidence of tubercle in either locally or in the adjacent organs. In these cases the following procedures were carried out

Exploratory laparotomy	8
Appendectomy	10
Hemicolectomy and ileotransverse colostomy	3
Hemicolectomy in patient with previous ileotransverse colostomy	1
Appendectomy with hysteropexy	1
Appendectomy with hysteradnexectomy	4
Excision of fecal fistula	1
Opening and tamponade of caseous abscess	1
	38

Twenty-eight patients were cured 7 showed improvement in their condition and 3 died. The authors arrived at the following conclusions

1 The preoperative diagnosis of tuberculosis of the appendix is almost impossible. It can be suspected in cases in which there are manifestations of tuberculosis elsewhere

2 Primary tuberculous appendicitis is very rare

3 Secondary tuberculous appendicitis is more frequent than the primary type but is not as frequent as reported by other authors.

4 Simple appendectomy has shown good results in only 1 case did a fecal fistula develop. Among the cases secondary to ileocecal tuberculoma (4) there was 1 death due to intestinal obstruction. Of those secondary to adnexal conditions (4) there was 1

death due to general spread with tuberculous meningitis

As regards operative procedures the authors state the following

1 Simple incision should be done in the presence of diffuse miliary or nodular lesions of the peritoneum

2 Appendectomy should be done in cases in which the lesions are prevalent over the appendix and the remaining visceral and parietal peritoneum shows few tubercular nodules

3 Right hemicolectomy followed by ileotransverse colostomy should be done in cases of tuberculoma of the cecum

4 Appendectomy and hysteradenectomy are the proper procedures in cases in which the adnexal tubercular lesions are extending into the appendix

The authors believe that their favorable results indicate that the pessimism of other workers is excessive when they insist on the necessity of respecting the appendix in the removal of tuberculous lesions

LUCIAN J. FAONOTTI, M.D.

Sulfonamide Therapy and Abolition of Drainage in Perforative Appendicitis with Purulent Peritonitis (Sulfamidoterapia e abolizione del drenaggio nelle peritoniti purulente da appendicite perforata) PARIDA STEFANINI and PASQUALE FIGARA. *Ann. Ist. Osp. Aquilani* 1946-47 1: 261

The literature is reviewed and reference is made to authors recommending drainage and nondrainage for perforative appendicitis with diffuse or localized peritonitis.

The authors then record their experience with appendicitis. From April 1940 through the year 1945 200 cases of acute appendicitis with perforation 43 with diffuse peritonitis, and 157 with circumscribed peritonitis were seen. All these were treated by appendectomy and drainage with a rubber gauge drain. In 19 cases of the localized peritonitis group the appendix was not removed.

During 1946 the authors treated 11 cases of acute appendicitis with diffuse peritonitis and 36 with localized peritonitis following a standardized routine as much as possible. In this series of cases all patients with acute appendicitis were operated upon immediately regardless of the stage of the disease. Local anesthesia (20 cases) was the most common followed 10 order by ether anesthesia (13 cases) sodium pentothal anesthesia (12 cases) and spinal anesthesia (2 cases).

A McBurney incision was used in all cases. After the appendectomy was completed 5 gm. of sulfonamide were injected into the peritoneal cavity and spread with the fingers. At first powdered sulfadiazine was used, later crystalline sulfadiazine furnished by the Americans was used. This was followed by closure in layers without drainage.

Postoperative care consisted of the intramuscular injection of 1 gm. of sulfadiazine every 3 hours or 8 gm. in 24 hours. In children the dose was reduced to 6 gm. a day or 1 gm. every 4 hours. This was con-

tinued until deslervence. The maximum total dosage was 36 gm. as a rule only 1 patient receiving 50 gm. and the average dose was from 20 to 24 gm. During the first days large doses of plasma and physiologic serum are used.

The postoperative course was much better than when drainage was used. There was 1 death among the cases of generalized peritonitis and no deaths among the localized cases. Complications were not frequent. Wound infections developed in 12 cases. There were 3 cases of pelvic abscess, 1 among the cases of generalized peritonitis in which case the only death resulted. There were no cases of obstruction as contrasted to 7 cases among the 100 patients treated with drainage. Other complications in the latter series with drainage were iliac abscess (1) subphrenic abscess (1) evisceration (1) pneumonia—fatal (2) pulmonary embolism—fatal (1) and phlebitis of the lower extremities (1) none of these complications were seen among the cases without drainage. The average length of illness was reduced from 23.0 to 11 days for the patients with generalized peritonitis and from 21.17 to 9.6 days for those with localized peritonitis.

The authors conclude that the improvements in the second series were due to the abolition of drainage and secondarily to the use of sulfadiazole.

LOUIS J. FROST, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Clinical Studies of Liver Function: The Hepatorenal Syndrome. C. ROBERT SCHMIDT and V. E. CHERRY.
Am J Surg 94:8 75 172.

The present study was undertaken with the view of evaluating certain preoperative and postoperative therapeutic measures directed at improving the functional state of the liver in critically ill, poor risk, surgical patients. Because of the high incidence of associated renal and hepatic insufficiency (hepatorenal syndrome) following operation an evaluation of the role of the liver in postoperative morbidity and mortality must of necessity include serial studies of both renal and hepatic function.

Vital organs of which the liver and kidneys are examples are characterized physiologically by large functional reserves—large factors of safety. It has been estimated that but one-fourth of the parenchyma of these organs functioning normally is sufficient to carry out bodily functions. Decomensation follows when functional reserves are exhausted. Laboratory tests fall into two categories: function tests such as the hippuric acid and urea clearance tests, and decompensation tests, such as determinations of nitrogenous retention or the quantitation of icterus. The former give insight to the state of functional reserve. The latter give an index of severity of parenchymal damage in an organ whose functional reserve has been depleted. There is no justification for the assumption that liver and kidney function are "normal" in a patient who is not jaundiced and

whose nonprotein nitrogen is within normal limits. This situation obtains not infrequently in patients who are without functional reserves and who are thrown immediately into decompensation by insult that would ordinarily be considered insignificant. Yet much of the present knowledge of the hepatorenal syndrome springs from such a premise.

Considerable supportive evidence of a postoperative liver kidney relationship is indirect. In many instances conclusions have been reached by a priori interpretation of hospital records and necropsy material. The functional state of the organs under indictment prior to the onset of pathologic decompensation was problematical or unknown. This is particularly true of kidney function. Bartlett has called attention to this shortcoming. Before postoperative renal insufficiency can be attributed to extrinsic origin appropriate tests which demonstrate previously existing normal renal reserve must be on record. There is a paucity of such data in hepatorenal literature.

The liver plays an important role in postoperative morbidity and mortality. Patients with evidence of subnormal liver function who responded poorly to specific measures directed at improving hepatic function were poorer surgical risks than those who responded favorably.

Patients who developed hepatic and renal insufficiency following surgery usually gave evidence of subnormal renal reserve prior to operation.

Diminished renal reserve plays a greater role in the development of the hepatorenal syndrome in surgical patients than is generally recognized. Knowledge of the blood nonprotein nitrogen is without information on renal reserve until such reserves have been depleted.

Transitory fall of blood pressure and anoxia in poor risk surgical patients should be anticipated during and after surgery. Preventive treatment is the most effective treatment of circulatory collapse.

Decholin sodium appears to have produced favorable results in the treatment of postoperative hepatic and renal insufficiency.

BENJAMIN GOLDMAN, M.D.

Anoxia and the Liver with Special Reference to Shock and Chronic Malnutrition. J. GILLMAN and T. GILLMAN. *S J M Sc* 94:8, 13-1.

The authors have made a very detailed and important study of the fat and glycogen-free vacuoles found in liver cells under certain conditions. Acute anoxia from any cause results in the appearance of these vacuolated cells in the liver within a few minutes of the onset of the anoxic state, the vacuolated cells are the morphological expression of a disturbance of liver metabolism due to anoxia or shock of any cause. This serves to emphasize the importance of the liver in the shock syndrome.

Reports from the literature are cited to show that in hemorrhagic hypotension and shock, the portal blood flow through the liver is profoundly depressed and this depression may be out of proportion to the

changes in the peripheral blood pressure. In one reported experiment, when the blood pressure was reduced to 30 mm. following hemorrhage 11 of 12 dogs survived after viviparation of the liver via the splenic vein while 15 of 17 dogs treated the same way except that blood entered the jugular vein instead of the splenic vein died after transfusion.

The authors found that the most potent stimulus for the formation of vacuolated cells in the liver was hemorrhage resulting in shock. However, similar vacuolated cells are found in other organs in acute anoxia and shock, the endocrines, striated muscles, heart muscle and brain may be similarly affected. Thus disturbances in functions of many parts of the body are all involved in the shock syndrome.

F. J. LEESEMAN JR. M. D.

The Differential Diagnosis of Jaundice. S. ALLEN WILKINSON *Surg Clin N America*, 1948, 43: 575.

In a particular case of jaundice the differentiation as to the type will usually be obvious from the history alone. There will be rare occasions when it will be impossible to decide whether or not there are enough features of obstruction to make it a surgical problem. In such cases it is better to operate than to temporize and usually a combined form of jaundice will be found.

The differentiation of hemolytic jaundice from the hepatogenous type is not difficult. The finding of a known toxic agent, the presence of an increased amount of bile and urobilinogen in the stools and of an increased amount of urobilinogen in the urine plus the absence of bile in the urine and normal liver function tests will usually make the diagnosis of hemolytic jaundice evident.

It is well known that there is no liver function test or group of tests that completely delineates the function of a liver.

The serum bilirubin determination is probably the most useful liver function test. The one minute bilirubin is said to measure the sodium bilirubinate present (the direct reaction) while the total bilirubin is an index of the sodium bilirubinate plus the bilirubin in the blood. Thus, the one minute bilirubin will be low or absent in hemolytic or retention jaundice because most of the bilirubin present is in the form of bilirubinogen. In severe hepatocellular jaundice or in obstructive jaundice the direct or one minute reading will be high as it will show most of the total bilirubin present.

The urobilinogen determinations are important helpful in differentiation and not difficult. Urobilinogen is formed almost exclusively in the intestine from bile reaching the intestine by way of the common bile duct. This intestinal urobilinogen is partly reabsorbed by the portal circulation, returned to the liver, and used by the latter in protein synthesis. If the liver is damaged much of the urobilinogen is passed on to the kidney where it is excreted. Hence an increase in fecal urobilinogen occurs in hemolytic jaundice, and an increase in urine urobilinogen occurs in most cases of liver damage and particularly in

TABLE L.—TESTS FOR JAUNDICE

Test	Retention Jaundice		Regeneration Jaundice		Normal Values
	Hemolytic Jaundice	Hepatocellular Jaundice	Obstructive Jaundice		
Bilirubin	1 min. (n.s.) low Total-high to 5 gm. %	1 min. (s) high Total-high to 5 gm. % (over 5 mg)	min High Total-high to 10 mgm %	1 min. to 3 mgm. Total-0 to 5 mgm.	
Urobilinogen Feces	High	Normal or low	Absent	3 to 4 gm. per day	
Urine	Slightly elevated	High	Absent	1 to 20 or less	
Serum protein Albumin-globulin ratio	Normal or low Normal	High Reversed	Normal Normal	5 to 7 gm. % 3 to 4 gm. % 1 to 1 gm. %	
Bromsulphalein, 5 mgm per kilogram dose	Normal	Dysretention	D ₂ retention	0% in 45 min.	
Cephalin flocculation	Normal	Positive	Normal (Any of these can become abnormal after liver damage occurs)	to plus (+)	
Thymol turbidity	Normal	Positive		to 3 units	
Thymol flocculation	Normal	Positive		0 to plus (+)	
Cholesterol	Normal	Normal or low	Elevated	20 to 30 mgm %	
Cholesterol ester	Normal	Low	Normal	60% of total	

portal cirrhosis. No urobilinogen will be found in the feces or urine if obstructive jaundice is present.

The tests based on serum colloids and electrolytes are not yet well understood. There has been a great deal written about the application and comparative value of the Takata Ara test, the cephalin-cholesterol flocculation test, the thymol turbidity test, the thymol flocculation test and the colloidal gold test. No one as yet has satisfactorily explained just what it is that these tests measure. On the other hand, everyone is agreed that they are very valuable tests and that they are among the most delicate and most reliable tests of liver dysfunction; however, no one of these tests covers all the various types of liver dysfunction. For this reason it is customary to order more than one on the basis that if they are all normal, the chances are very good that the liver function is normal. These tests offer a valuable check on the progress of liver disease and when they show a final return to normal we have the best evidence that the pathologic process has finally subsided. They do not offer any differentiation between intrahepatic and obstructive jaundice but they are likely to be normal in hemolytic jaundice. In early obstructive jaundice they will also show normal findings but these will change quickly as damage to the liver occurs consequent to back pressure in the biliary tree.

The serum cholesterol value combined with a cholesterol ester determination is sometimes of definite value. In obstructive jaundice the total cholesterol is increased. In hepatocellular jaundice, first the esters and later the total cholesterol may be much decreased. In fatal cases they will fall almost to zero.

CAR. O. LATIMER, M.D.

Studies on the Pressures within the Common Bile Duct. Postoperative Cholangiomanometry (Estudios sobre la presión intracolecística. Colangiomanometría pos-operatoria). RENO B. FERRACANE. *Cirugía* 947 37.

The author who has been working on pressures in the bile passages under the direction of Adrián J. Bengole since 1938, uses a water manometer connected up with a Kehr tube or a Petzer sound. This tube is attached to a apparatus making permanent graphs on a chart graduated in centimeters. The normal figures for pressure oscillate between 0 and 6 to 8 cm. of water, the values undergoing transient physiologic variations.

Under pathologic conditions such as residual lithiasis in the common bile duct, pancreatitis, or even a spasm of the sphincter of Oddi the biliary pressure tends to remain elevated for prolonged periods and may be accompanied by symptoms of biliary colic. The spasmodic or other occlusive condition may also be demonstrated by injecting colored fluids and observing the delay in their elimination into the duodenum by means of aspiration through the duodenal tube. The hypertensive condition tends to be relieved by injections of atropin or the administration of amyl nitrite and induced or intensified by the administration of morphine, eserine or pilocarpin.

The author concludes that the measuring of the intrabiliary pressures constitutes a valuable method for the study of the function of the terminal portion of the choledochus especially when accompanied by pressure perfusion and by concurrent cholangiographic studies.

JOHN W. BRENNAN, M.D.

The Effect of the Ligation of the Pancreatic Ducts and of Pancreatectomy After Duct Ligation on Serum Lipase. MARTIN M. NOTEN, T. DYKENS, PRATT and JOSEPH BENNETT. *J. Lab. Clin. Med.* 943, 33 833.

In an effort to establish experimental proof of the clinical value of the serum lipase test, the authors have repeated part of the work of Cherry and Crandell and have contrasted their results with the conflicting reports of Popper and Sarter.

An attempt is made to answer the questions: (1) Is there an increase in serum lipase after pancreatic duct ligation? (2) If there is an increase in serum lipase is it pancreatic or extrapancreatic in origin? (3) What is the mechanism of the increase of the serum lipase found in duct ligation?

The normal serum lipase values (olive oil-emulsion titration method) were established for 26 dogs. The average was found to be 0.6 units. After ligation of

all pancreatic ducts, the 24 hour average was 5.1 units (a value 13 times normal). The 48 hour average was found to be 7.0 units and after 6 to 7 days there was a tendency for values to decrease. This seems to answer the first question and to prove that after ligation of the pancreatic ducts there is almost invariably a rapid rise of the serum lipase which lasts a relatively long time. Moreover complete pancreatectomy in 3 dogs resulted in an immediate decrease in lipase and eventual death. These data substantiate the idea that lipase originates in the pancreas.

The evidence for the extrapancreatic source of the lipase enzyme was the recurrence of normal serum lipase values in 3 to 3 weeks after total pancreatectomy in 2 dogs in which preliminary ligation of the pancreatic ducts had been done.

As to the mechanism of the increase, a pancreatic fistula was formed of a portion of the pancreas, the ducts of which had all been ligated. The previously elevated serum lipase values associated with ligating the ducts dropped to normal when the pancreatic secretion was liberated.

The authors conclude that the mechanism of elevated lipase levels in the blocking of the ducts (ligating) is due to absorption of the enzyme into the blood after ligation.

JANE C. MACMILLAN, M.D.

Carcinoma of the Pancreas: Diagnostic Criteria. GRAYSON F. DARRILEL and WALTER LINDCOLN. *P. L. Med. Arch. Int.* 11 1943, 811 173.

The preoperative diagnosis of carcinoma of the pancreas is still a difficult one, and the authors attempt to bring out diagnostic criteria that will aid in an earlier recognition of the disease.

The group here reported comprised 90 patients. The average age was 55.0 years and the sex ratio was 9 men to 1 woman. The chief complaint was pain followed in frequency by jaundice, loss of weight, anorexia, constipation, nausea and vomiting. The average duration of symptoms was 4.7 months.

The pain was gradual in onset and varied in location and quality but was usually steady. In many cases the pain was more severe when the patient was in the supine position. The most frequent sites of pain were the epigastrium, the upper abdominal quadrants, and the back. Jaundice was present in 66.6 per cent of the patients. As a rule the jaundice was pronounced and progressive, although in one case the jaundice did subside. Considerable loss of weight occurred in all cases. Twenty-four patients suffered nausea and vomiting and diarrhea was present in 18 patients. Steatorrhea was uncommon. The gall bladder was palpable in 54 per cent of the jaundiced patients. Glycosuria, usually in constant occurrence in 27 per cent of the cases, and a diabetic type of dextrose curve was found in 18 of 22 patients tested. The diagnostic value of this procedure may be greater than has been realized.

Röntgenologic examination may enhance the chance of a correct diagnosis. In this series evidence suggestive of the lesion was present in 35 of 79 pa-

twelve examined. The signs most commonly found were irregularities in the duodenal contour distortion and displacement of the stomach, deformities of the duodenal bulb and expansion of the duodenal loop. Lesions of the body and tail are less likely to produce roentgenographic signs than those of the head.

The authors comment on the importance of evaluating these signs and symptoms, and repeat the old injunction to "keep the disease in mind."

ELY ELLIOTT LAZARUS, M.D.

Surgical Conditions of the Spleen. FRANK H. LANEY
Surg. Clin. A. America 1948 28, 559.

After briefly considering what is known of the physiology of the spleen the author classifies the splenic states in which splenectomy is indicated and splenic states in which the indications are not all ways clear.

The splenic states in which splenectomy is indicated are as follows: rupture of the spleen, ptosis and torsion of the spleen, cysts of the spleen, tumors of the spleen, abscess of the spleen, malarial spleen, and when splenectomy is included in total gastrectomy.

The splenic states in which the indications for splenectomy are not always clear are as follows: familial hemolytic jaundice (hereditary), idiopathic thrombocytopenic purpura, splenic neutropenia, primary splenic panhematocytopenia, Banti's disease (with limitations), Gaucher's disease (selected cases) and Hodgkin's disease (selected cases).

Since the spleen rests directly over the upper surface of the kidney, one should never fail, should operation be undertaken for a ruptured spleen, to investigate the kidney, since any force capable of tearing off or rupturing the blood supply of the spleen must in its course also be delivered to the region of the left kidney and may also rupture this organ. Wide incision (the author uses a long left rectus incision) and good anesthesia, particularly the added relaxation obtained with curare, make it possible to control the hemorrhage and visualize the front surface of the kidney and the adrenal gland following removal of the spleen. Left nephrectomy may be done through the incision if necessary.

Ptosis and torsion of the spleen, cysts, abscesses and malarial spleen are uncommon lesions. Tumors exclusive of lymphomas are rare. Lymphosarcoma and Hodgkin's disease are the more frequently encountered tumors.

The author includes splenectomy in a great many if not the majority of the transthoracic resections for malignancy of the lower end of the esophagus or the upper end of the stomach. Also splenectomy is usually combined with total gastrectomies. The best way to add omentumectomy and total gastrectomy is to leave the spleen attached to the omentum to ligate the splenic vessels, to leave the vasa brevia running from the spleen to the stomach unsevered, thus there is complete removal of all of the greater omentum and with the stomach turned up it is possible to include also all of the gastrohepatic omentum with ligation of the gastric artery close to its origin. A review of the cases in which splenectomy has been included in these procedures has shown no bad effect on the blood picture.

Among the conditions in which the indications for splenectomy are not always clear congenital hemolytic jaundice stands out as the disease in which splenectomy is most consistently satisfactory. If the operation is not undertaken during an acute episode and if the gall bladder which contains stones is also removed, recovery from the anemia and relief from the jaundice occur usually without other treatment.

Idiopathic thrombocytopenic purpura is rarely associated with significant enlargement of the spleen and the spleen may actually be of less than normal size. So excellent and consistent are the results following splenectomy in this condition that when they are not good the correctness of the diagnosis is questionable. Once the diagnosis is established splenectomy should not be delayed.

Primary splenic neutropenia and primary panhematocytopenia respond satisfactorily to splenectomy. In these cases of panhematocytopenia in which the condition is secondary to other lesions the improvement will be definite but temporary.

While splenectomy in Banti's disease is not consistently followed by satisfactory results splenectomy is indicated if the diagnosis can be made early, because of its propensity at least to decrease the load on the portal circulation and the possibility that it will defer or prevent the hemorrhages associated with esophageal varices and delay the development of portal cirrhosis.

The author has had one case of Gaucher's disease in which splenectomy was performed. The results have been quite good temporarily.

LARRY C. LATTIMER, M.D.

GYNECOLOGY

UTERUS

Uterine Cancer: Its Early Detection by Simple Screening Methods. DANIEL J. MCSWENEY and DONALD G. MCKAY. *N. England J. M.* 1946, 238: 867

For one year the authors have conducted a clinic for the early detection of cancer of the uterus at the Boston City Hospital. This "screening" process consists of a careful gynecological history with special attention to abnormal bleeding and vaginal discharges, a pelvic examination, a speculum examination and a vaginal smear. The last is most valuable as a test to determine cases that may require diagnostic curettage or cervical biopsy. Cases that are positive on smear or suspicious on smear history or pelvic examination are subjected to biopsy by curettage, cervical biopsy or both.

The technique and a brief description of the cellular characteristics are given.

The authors believe this method of screening is simple and efficient and definitely aids in the diagnosis of carcinoma. The degree of accuracy of course depends on the care with which the smears are taken and the training and experience of the cytologist.

Of 54 cases of cancer 51 were diagnosed correctly by smear.

Six cases of carcinomas, which might otherwise have been neglected, were detected by the vaginal smear technique and 6 others were detected simultaneously by biopsy and smear. T. FLOYD BELL, M.D.

Sarcoma of the Uterus. THOMAS PERRY JR. *N. England J. M.* 1945, 235: 703.

The author reports 4 cases of sarcoma of the uterus in detail. These are part of a group of 18 cases seen during the past 18 years at the Rhode Island State Hospital, Providence.

In a review of the subject of uterine sarcoma, it is pointed out that sarcomas may arise both in the smooth muscle of the uterus and in the stromal cells of the mucosa. The author also emphasizes that all reports show a preponderance of leiomyosarcomas over other forms of uterine sarcoma. The stromal or mucosal cell cancers of the endometrium are characterized by round cells rather than by spindle cells as found in typical leiomyosarcoma. The author also includes in this group the various types of mixed tumors which, despite their pleomorphism, presumably arise from stromal cells or their anlage. There are in this group mixed mesodermal tumors which contain more than one type of tissue of mesodermal origin. There are those which contain tissue of mesodermal origin and epithelium and are referred to as carcinosarcomas. A large proportion of stromal cell tumors, if carefully examined, show a mixed histology. All these sarcomas tend to contain giant cells.

Hemangiosarcoma and botryoid sarcoma are rare types. The botryoid type is most frequently seen in

the cervical portion of infancy, and presents a mixed histological pattern which includes epithelium, myxomatous tissue, striated muscle and other elements.

Most patients with uterine sarcoma have advanced disease after the onset of symptoms and radiation therapy invariably is useless. The author found that in the study of his group of patients there was a direct relationship between the number of mitotic figures and the rapidity of growth. It was found that in the larger tumors the areas which were more anaplastic were larger. Total abdominal hysterectomy with bilateral salpingo-oophorectomy is the treatment of choice. The chief cause of the low survival rate is the silent nature of many of the tumors. None of these tumors seem to arise in the cervix. The author thinks that most of them are malignant from inception and rarely arise in myomas.

The botryoid type usually arise in the portion of the cervix and extend down into the vagina. Striated muscle fibers in this tumor are considered pathognomonic.

It was advanced by Wilms, in 1899, that the mixed sarcomas of the uterus originate in displaced myotome and sclerotome elements which are carried down by the wolffian ducts.

HENRY C. FALK, M.D.

Additional Data in the Technique of Vaginal Hysterectomy. N. SPROUL HEARTY. *West. J. Surg.* 1945, 56: 377.

After briefly relating the history of vaginal hysterectomy the author presents his method of procedure.

Since the operation may be difficult with the ordinary instruments used in abdominal work, a list of more suitable armamentarium is given. Two assistants are required. The operation is described in detail.

Shock occurs only rarely and usually the loss of blood is small. The intravenous administration of saline and blood transfusions are not given routinely. Patients are urged to sit on the edge of the bed with the feet in a chair the day after the operation, and to sit out of bed the following day. They are allowed to go to the toilet with help and are discharged from the hospital one week after operation.

T. FLOYD BELL, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

The Characteristics in Hysterosalpingograms in Tuberculous Salpingitis and Endometritis. KO-CAN SYU. *Am. J. Obs.,* 1945, 55: 933.

Unique and fairly constant topographic characteristics are seen in the hysterosalpingograms in tuberculous salpingitis and endometritis. The salient features are summarized:

1. In the plain films made before the injection of contrast medium in 4 of 6 patients, opaque bodies

were seen in the pelvis. In 2 cases fibrocalcareous adhesions were visible.

1 The filling of the uterine organ and the tubes was rather tardy. In the filling no sign of contractions was apparent. When filled the cervical canal exhibited a fuzzy shadow which has been described as "manlike or feathered by various workers. The uterus appeared like a trumpet or a Voothees balloon, and its borders were shaggy and jagged. Its fundic shadow was invariably convex, and its lateral contour likewise bulging. The tubes, if filled were filled in a jerky fragmentary fashion so that their entire contour appeared to be beaded, segmented, and fractured. They were stiff wiry thready and drooped downward like a filament. There was often an abrupt ending of the filling process. The fimbria were pouchlike, saccular and diverticular in shape.

3 The appearance of the entire contrast medium was uneven nonhomogenous and simulating for eign bodies.

4 The stationary manner or the lack of spread of the contrast medium in the free peritoneal cavity, and the frequent complete emptying of the filled tubes after 24 hours were quite characteristic.

5 The imperfect filling of the organs might mislead one to think of a hypoplastic or a malformed uterus.

The pathogenesis of these characteristics is discussed and an outline of the differential diagnosis by means of hysterosalpingograms in various diseases is presented.

The presentation does not mean that all cases of tuberculous salpingitis and endometritis would present all the characteristics in the hysterosalpingograms. Never should one entertain the idea that tuberculous salpingitis and endometritis can be diagnosed by means of roentgenograms alone.

JOHN R. WOLFF, M.D.

Ovarian Fibroma with Ascites and Hydrothorax.
NIC. CLEMETSON *Acta obst gyn scand.*, 1948, 28
96

Meigs syndrome has been noted in patients with other ovarian growths than fibroma. Its occurrence is infrequent, and the majority of some 50 published cases are to be found in the American literature. Only about half of these tumors are complicated by ascites.

The ovarian fibromas which form parts of Meigs syndrome vary in size from orange sized to larger than a man's head. They are mostly unilateral. In shape they are round or oval. The surface is often crinkled white or whitish yellow in color in most cases smooth and mirrorlike. They are hard often with larger or smaller cavities.

Microscopically they are seen to consist of fibrous connective tissue with many collagen fibrils. The cavities are usually without epithelium.

The ascitic and pleural fluid which is usually found in large quantities is as a whole slightly turbid or of a yellow to reddish color, and contains varying numbers of mononuclear and red blood cells.

Most of the patients with Meigs syndrome whose cases have been reported were from 40 to 50 years of age.

The most frequent symptoms are those referable to the chest, such as shortness of breath, stitch in the side and cough. Next in frequency among the symptoms is enlargement of the abdomen.

Treatment consists in laparotomy and extirpation of the tumor.

As to the cause of ascites the theory now generally accepted is that the greatest part of the ascites is formed in the tumor itself on account of circulatory disturbances. The production of ascites is too great in proportion to the capacity of the draining apparatus.

With the support of Efskind's experimental investigations respecting absorption in the peritoneum of rabbits and on the assumption of similar conditions in man the author submits the hypothesis that the lymphogenous drainage of the ascites takes place preferentially through the right part of the diaphragm via subpleural lymph vessels to the anterior intercostal lymph glands and therefrom further over into the blood vascular system.

If outflow from the anterior intercostal lymph glands is impeded, lymphostasis will arise and result in hydrothorax, especially on the right side.

One case is presented. T. FLOYD BELL, M.D.

Six Cases of Primary Carcinoma of the Fallopian Tubes. LUDWIG A. EMOR. *West J Surg* 1948
56-554.

The author presents 6 cases of primary carcinoma of the fallopian tubes. There was a 0.3 per cent incidence of tubal carcinoma among 2,000 tubes removed from 2,000 patients.

It is observed that primary tubal cancer is not only insidious and vicious in its growth habits but most confusing in its symptomatic manifestations. Large and localized malignancies often remain asymptomatic. Commonly they are confused with ovarian malignancy. Some authors state that the diagnosis should be thought of when pelvic inflammatory disease occurs at an age when tubal infection is rare but malignancy common and there is a sudden appearance of profuse uterine discharge not explainable by cervical or uterine disease. The manifestation of repeated discharge as seen in hydros tubae profuens is not a common finding.

The author believes that the vaginal technique of examining vaginal discharge is more apt to facilitate recognition of all pelvic cancers. Hysterosalpingography is not safe.

All 6 patients observed were dead in 20 months. The gross and microscopic appearance of the malignant tubes removed conformed to that described by other observers with regard to types and cellular composition.

Primary cancer of the fallopian tubes remains grossly localized for a considerable length of time provided the fimbria closes before the disease spills into the pelvis. The well known resiliency of the tu

lial wall permits enormous extension before the muscular layers are invaded. Lymphatic extension probably occurs long before extension of the growth affects the tubal wall. The grading of tubal cancer is not wise because all grades may be found in the same tube. The grade of cellular differentiation in no way allows for prognostication. The treatment is surgical and as radical as possible.

HENRY C. F. LEAL, M.D.

Normal and Cystic Structures of the Broad Ligament. GEORGE H. GARDNER, R. R. GREENE, JR.
B. 31 *PSYCHIA* 1m J *Obst* 948 55 97

The literature on cysts of the broad ligament was reviewed in an attempt to find or to formulate an accurate classification of these structures. Because of the terminologic as well as histologic overlap and embryologic diversities encountered it was decided to study the embryonic development of broad ligament structures, the normal adult broad ligament, both in routine and in serial section and, finally, the abnormal broad ligament. That portion of the study having to do with the histogenesis of cysts of the broad ligament is presented. The embryology and the normal and abnormal structures of the adult broad ligament are given. A simple classification based on histogenesis is proposed.

The authors believe that much of the existing confusion in classifying normal and cystic structures of the broad ligament can be eliminated by discarding terms based on proper names and using those having histogenic significance.

Certain well developed structures derived from the embryonic mesonephros are present in the adult broad ligament and can be demonstrated in properly fixed, sectioned, and properly prepared tissues.

Mesonephric ducts, mesonephric tubules, and paramesonephric structures, as well as their respective cystic derivatives, have an individual and a characteristic histologic appearance each can be identified with ease.

It is possible to classify most cysts of the broad ligament on the basis of the character of their lining epithelium but it is impossible to classify them accurately on the basis of their location in the ligament.

JOHN R. WOLFF, M.D.

MISCELLANEOUS

The Use of the Vaginal Speculum in a Gynecologic Service. LOCKE L. MACKENZIE, BEN R. WETTERLIE.
JOHN C. DUBOIS, AND THEODORE NEUBAENDER.
4m J *Obst.*, 948, 55 8

At the New York Post-Graduate Medical School and Hospital New York, New York the vaginal

speculum has become a distinct addition to the diagnostic resources. It is not suggested that it supplants the well established diagnostic methods such as physical examination, biopsy and biologic hormonal assays and tests, but vaginal smears are used in association with the others and a proper amount of credence is placed on the interpretation.

The technique is particularly useful in evaluating endocrine disorders in women. The diagnosis of malignancy of the female genitalia can be made in a high percentage of cases and the method should be more widely used for this purpose.

All efforts should be directed toward an attempt to establish a smear criterion of premalignant change.

JOHN R. WOLFF, M.D.

Implantation of the Ureters into the Rectosigmoid in Case of Urethrovesicovaginal Fistula (L'impianto degli ureteri nel sigma-retto nelle fistole uretro-vesico-vaginali). AUGELLO DE PAOLO. *Quad. chir. ital* 918. 947 2: 883.

The following indications for ureterovesicovaginal anastomosis are listed by the author in order of their importance and frequency: urethrovesicovaginal fistula; vesicovaginal fistula with extensive destruction of tissues; grave trauma of the urinary bladder; radical atrophy; difficulties encountered in ureterocystostomy following an injury of the ureters during obstetrical or gynecologic operations. The last mentioned injury of the ureters occurs relatively frequently in the course of a total hysterectomy for cancer of the uterus or for an intraligamentary fibroma. Such an injury may also complicate removal of the adnexa, which following inflammatory processes form adhesions to the pelvic peritoneum.

In the case reported by the author a vesicovaginal fistula appeared in a woman aged 24 on the fourth day of the puerperium following a spontaneous, normal delivery at term.

The physical examination disclosed an extensive vesicovaginal fistula involving the trigonum, with nearly complete destruction of the urethra. An attempt to repair the urethra through the vaginal route, 9 months after the delivery, failed. Thirteen months later the physical examination showed a nearly complete destruction of the anterior vaginal wall without traces of the urethra.

The ureters were implanted into the rectosigmoid area according to a slightly modified Hinman's technique under spinal anesthesia. The operation was performed in 2 stages, 5 weeks apart; one ureter being implanted each time.

The immediate and late results, checked with descending pyelography, were excellent.

JOSEPH K. NARA, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Hemoconcentration in Obstetrics (La hemoconcentración en obstetricia) LUIS TRINCE BROUSSE Y ORLANDO TRIVELLI ROCCHI *Bol Soc chilena obst gín* 1947 12 303

The author found from his experience in 450 examinations with the Wintrobe hematocrit in pregnancy and the puerperium that the blood concentration was about 40 which suggested that there is a condition of hydremia during the gravid state which varying with the individual is greater than that commonly encountered in nonpregnant women. However numerous factors have an influence on this condition of hydremia and the test is found to represent another aid in the clinical examination of the patient and a guide to diagnosis and therapy.

Perhaps the most important condition to be looked for is the blood concentration leading to shock which may be present preceding the operation or during dystocia in patients who have been subjected to a low fluid salt free diet such as is commonly prescribed for the edematous renal or cardiac conditions encountered during the period of pregnancy.

The preoperative determination of the erythrocyte volume is also very important since the blood concentration may already be high (preshock condition) because of prolonged labor or a low fluid diet and the extra load placed on the organism by the operation may produce an irreversible condition. In such a contingency the patient must be given fluids even during the postoperative period because the natural tendency toward a restricted regimen can easily eventuate in an unnoticed concentration which may lead to shock.

JOHN W BRENNAN M.D.

Pernicious Anemia of Pregnancy and the Puerperium. L. S. P. DAVIDSON, R. H. GIRDWOOD and J. R. CLARK *Brit M J*, 1948 1 819

The authors state that Addisonian pernicious anemia is uncommon, but that pernicious anemia of pregnancy is rarer still. Of 521 cases of macrocytic anemia examined in the last 7 years, only 35 were associated with pregnancy and of these only 4 were seen since the introduction of folic acid. No reports have appeared in the British literature and only 4 cases have appeared in the American literature on the therapeutic value of folic acid in this type of megaloblastic anemia (3 by Spies in 1946 and 1 by Moore *et al* in 1945). Folic acid was given in all cases by the parenteral route and in all cases a satisfactory response was obtained.

In the present article the authors report 3 cases of pernicious anemia of pregnancy and 1 case of Addisonian pernicious anemia that relapsed as a result of pregnancy all of which responded to folic acid.

The works of Stevenson (1938), Callender (1944) and Davidson, Davis and Innes (1942) are cited.

Davidson and Davis (1947) noted four points of particular importance in the diagnosis of pernicious anemia in pregnancy.

1 The demonstration of typical megaloblasts in the bone marrow since the peripheral blood picture may differ from that of Addisonian pernicious anemia, the color index may be below one and the M.C.V. within normal limits.

2 Although free hydrochloric acid is often present in the gastric juice in a number of cases, a histamine fast achlorhydria is found. Unless the effect of stopping liver therapy is observed for a period up to 2 years it is difficult to decide whether it is a case of pernicious anemia of pregnancy or Addisonian pernicious anemia complicated by pregnancy.

3 The response to parenteral liver therapy may be normal poor and delayed or absent.

4 Cases refractory to parenteral liver therapy will respond to oral treatment with proteolysed liver or to cooked liver (Fullerton 1943).

No adequate explanation for the development of pernicious anemia of pregnancy has been forthcoming. Possibly it is a failure of some intake factor from a failure of production of Castle's intrinsic factor or defective absorption from the alimentary tract.

The authors suggest folic acid as the treatment of choice because it can be administered by mouth and shows rapid hematological improvement. Since the treatment is limited to a few weeks the danger of producing subacute combined degeneration of the cord is greatly reduced as compared with Addisonian pernicious anemia. However they state further that time must elapse before it can be stated confidently that neurological features will not occur in patients with pernicious anemia receiving folic acid.

The authors also warn that many cases of pernicious anemia of pregnancy also suffer iron deficiency and this must be corrected accordingly.

BYRON F. HEARST M.D.

Leucemia and Pregnancy JOHN A. WILLIAMS *Am J Obst* 1948 55 967

The coexistence of leucemia and pregnancy is rare. A review of the literature together with 2 cases added in this report brings the total number of reported cases of pregnancy associated with leucemia to 90.

A case of chronic myelogenous leucemia complicated by pregnancy with the mother still living more than a year after delivery is presented.

A fatal case of acute monocytic leucemia complicating pregnancy with a discussion of autopsy findings is presented. No similar case has been found in the literature.

With critical review of the literature it is safe to conclude that pregnancy has little if any effect on the course of leucemia. Leucemia per se does not require any special obstetric management.

Premature labor has been seen in the majority of cases, but severe hemorrhage, postpartum or during delivery by any method has been uncommon—9 instances among 88 patients with 3 deaths.

JOHN R. WOLFE, M.D.

The Possible Significance of Arterial Visualization in the Diagnosis of Placental Previa LEO J. HARTWELL *Am. J. Obst.*, 94:5, 551-540.

Arteriography is a method by which the outline of arteries may be seen on x-ray plates following the injection of radiopaque substance. This procedure has been carried out on almost every organ and region of the body. It was conceived that by delaying the time of exposure following the injection of opaque solution into the aorta, the maternal circulation over the placental site might be visualized by roentgenography. This procedure was carried out on 65 women in the later stages of pregnancy. The technique is given in detail.

All women in this series delivered without mishap and all babies were living and apparently unaffected. Mothers and infants were released from the hospital after the usual routine lying in period.

Two cases of bleeding were encountered, one at the thirty-first week of pregnancy and the other at the twenty-eighth week. Aortograms were performed on these patients with no ill effects. In both instances there was a question as to the cause of bleeding.

If the bleeding had been produced by the separation of a low-lying placenta, the attendant danger to the mother and baby would have been less than had it been produced by an abruptio placentae. Since the hemorrhage in both instances, was profuse and sudden in onset gradually subsiding, the aortograms proved very useful when making a decision as to treatment.

In considering whether the risks involved in aortography are worth while in comparison with the hazards of watchful expectancy, the author believes that the series is not large enough for him to come to a definite conclusion. It appears evident that the procedure is sound and that the failures have been the result of errors in technique rather than a lack of fundamental soundness. JOHN R. WOLFE, M.D.

Chorea Gravidarum: Review of the Recent Literature and Report of 5 Cases. THOMAS W. McELIM, SAM B. LOVELAND, and HENRY W. WOLTMAN. *Am. J. Obst.* 94:5, 55-99.

Chorea gravidarum is an infrequent complication of pregnancy. However, though rarely observed it occasionally presents a grave problem.

Data from 13 American hospitals suggested a hospital incidence of 1 case per 3,500 obstetric admissions, although this may be an exaggerated concept of the frequency of this complication, since of 170 obstetricians replying to their questionnaire 113 had never observed a case.

The average age of the patients was 24 years. Chorea associated with pregnancy was observed much more frequently in primigravida patients. An

illegitimacy rate of 17.2 per cent was observed. The authors commented on the rarity of this factor in the Negro race.

The well known syndrome consists chiefly of hypermotility and incoordination which is usually generalized. The movements usually cease during sleep. The patients are usually afebrile and when fever does occur it is of ominous significance. Hyperpyrexia can occur.

The most frequent complications were stated to be acute psychosis, acute endocarditis and rheumatic fever.

Authors whose articles were reviewed warned against the excessive use of depressant drugs. The prophylaxis of chorea gravidarum consists of proper prenatal care. The treatment consists of keeping the patient at rest in bed and the administration of sedatives. Emptying of the uterus should be considered if the patient's condition becomes progressively worse. Local anesthesia should be used whenever possible and a neurologist should always be consulted.

The authors found it impossible to draw any significant conclusions from the small series of 5 cases observed at the Mayo Clinic, which they presented. In all of these cases chorea began in the first half of pregnancy and lasted for periods varying from 2½ weeks to 5 months. All of the pregnancies were terminated spontaneously at term and 6 normal babies were born (1 twin pregnancy).

Only 1 patient, whose condition might have been described as moderately severe, required hospitalization while under their care.

No evidence to support a toxic etiology of this condition was present in this series, other than perhaps the nausea and vomiting mentioned in 3 cases. A rheumatic background was present in all of the cases. A past history of chorea was given in 3 cases and of rheumatic fever in 3 cases. Heart disease was present in 3 cases.

The recent literature concerns 5 chorea gravidarum is considered. Reference is made to the toxic, allergic, rheumatic, infectious, and psychogenic hypotheses of origin of chorea gravidarum. The current status of authoritative obstetric opinion is reviewed. The case for a rheumatic etiology of this condition is further strengthened by the 5 case reports. A suggestion of psychogenic "color" was present in this series. Conservative methods of treatment and delivery were used in all cases. A successful outcome of the pregnancy occurred in all instances.

LABOR AND ITS COMPLICATIONS

The Duration of Labor: Mean, Median, and Mode. TERRY BURRY *Am. J. Obst.*, 94:5, 55-84.

The figures cited in textbooks for the duration of labor are 18 hours in primigravidae and 12 hours in multiparas. These are mean or average values calculated simply by adding up the total hours occupied by all labors in a large series, and dividing by the number of labors. Although mean or average figures

OBSTETRICS

are often valuable, they may sometimes be very misleading and not truly representative. The incidence of prolonged labors tends to distort the actual average figure.

The median and modal durations of labor are more statistically significant than the mean or average and certainly more in keeping with the experience of obstetricians. In white primiparas, the mean was found to be 13.04 hours, the median 10.59 hours and the mode 7 hours. In white multiparas the mean was 8.15 hours, the median 6.21 hours and the mode 4 hours.

The average duration of labor is longer in negro than in white patients, because of the greater incidence of prolonged labor in the former. Recent improvements in obstetrical technique and prenatal care have significantly shortened the average duration of labor.

JOHN R. WOLFF, M.D.

The Treatment of Placenta Previa (Consideraciones sobre tratamiento de la placenta previa) JORGE ROUSSELL GONZALEZ. *Bol. Soc. chilena obst. gín.*, 1947, 13, 310.

In this dissertation (on the occasion of the author's enrollment as a member of the Chilean Obstetrical Society) the therapeutic implications gleaned from a statistical consideration of the results obtained in 403 cases of placenta previa in 41,693 births (0.96 per cent) at the Maternidad del Salvador in Santiago de Chile are discussed.

No decisive conclusions are drawn as to the benefits to be expected from the introduction of the sulfonamides and penicillin since the period of their usage has been so short; however a favorable effect has been noted not so much in regard to morbidity as to the incidence of more serious infections which endanger the life of the mother. In fact, during the recent years there has been only 1 death among the mothers with placenta previa and in this case the woman presented a hopeless condition of perfringens septicemia when received in the clinic.

The encouraging control of the infections fixes our attention on the manner of the infections now can be foretold with any certainty—other than that they will certainly occur—and the only prophylaxis at present seems to be the removal of the contents of the uterus with resort to all of the modern resources for combating the anemia and other complications.

Cesarean section seems to be the only definitive recourse for placenta previa centralis totalis and this operation is indicated as soon as the diagnosis of this condition is made. Delay to await a more secure viability of the fetus is not to be considered, especially at present when modern progress in pediatrics offers greater chances for the immature infant, because it endangers both the mother and child.

For the other forms of placenta previa, cesarean section may on occasion be avoided however even in these cases the more radical procedure may be amply justified. So many factors intervene in these

patients that it seems impossible to lay down definite rules for their treatment. The one invariable rule is that these patients should be in a hospital from the instant of the first bleeding until the child is delivered. Here the viability of the fetus may rate some consideration since the mortality rate among infants weighing less than 2,500 gm. is very high. Of 213 dead babies 134 weighed less than this amount.

During the discussion ROGELIO RODRIGUEZ B. related the use of the forceps of Willett in some instances in which the bleeding had persisted after the rupture of the membranes in placenta previa centralis partialis.

HECTOR CABRERA does not agree with the author as to the technique of the cesarean section itself. The author reports the use of corporeal or segmental corporeal type of incision in 30 per cent of cases. Cabrera, on the other hand reports 513 operations done at the Maternidad of San Fco. de Borja with only 2 corporeal incisions, and the only death from peritonitis occurred in one of the 2 patients with this incision. The low incisions frequently passed right through the areas of implantation of the placenta without detriment to either mother or child.

MANUEL MORENO states that it is not the type of placenta previa which is important but the quantity of blood lost and the grade of anemia produced. In this respect the determination of the hemoconcentration is important.

Spinal (Saddle Block) Anesthesia in Obstetrics. G. J. ANDROS, WILLIAM J. DIECKMANN, P. OTDA, H. D. FIDDLE, AND OTHERS. *Am. J. Obst.*, 1948, 55, 806.

This is the study of 719 cases of modified saddle block anesthesia carried out at the Chicago Lying In Hospital, Chicago, Illinois. The procedure has been found to be safe, simple and precise. The degree of success has been high. The rate of operative interference in delivery was not significantly increased. Complications attributable to the anesthetic procedure have not been a problem. The benefits to the fetus in early spontaneous respiration have been striking. There has been no increase in the fetal or maternal morbidity or mortality.

JOHN R. WOLFF, M.D.

PURPERIUM AND ITS COMPLICATIONS

Acute Purperal Mastitis. H. CLOSE HESSELTINE, CHARLES G. FRAUDENICHL, AND K. EILEEN HITE. *Am. J. Obst.*, 1948, 55, 778.

Acute mastitis is a serious medical and surgical complication of the puerperium especially if suppuration occurs. Early treatment of the condition may often bring about subsidence without suppuration. Many reports indicate that penicillin will aid recovery. Somewhat different results observed at the Chicago Lying In Hospital, Chicago, Illinois, have stimulated the present report.

Two hundred and ten patients having suppurative purperal mastitis were observed. Suppuration was

observed in 6 of 33 consecutive patients with mastitis who were receiving penicillin therapy. Eleven strains of staphylococci isolated from the suppuration grew in the presence of penicillin.

After nursing the local use of ointment containing penicillin failed to affect the incidence of mastitis.

Nasopharyngeal cultures from mothers and babies were examined for the staphylococcus aureus. Twenty-one of 30 babies were found to harbor this organism during the first 10 days of life as did 20 of the 30 mothers. Ten of the strains were resistant to penicillin in vitro.

The present work indicates that infection of the breast may occur in lactating mothers from the patient herself or from the nursing infant. The importance of the nasopharynx has been stressed. The resistance of the organism to penicillin therapy is certainly a factor in the development of suppuration.

MISCELLANEOUS

Therapeutic Abortion: Medical Considerations.
HORACE M. KORNH / *J Am M Ass* 948, 37 333

This article concerns itself with heart disease as a complication of pregnancy. Hypertension of the regressive type is considered to be a definite contraindication to pregnancy. However, in the types of hypertensive diseases in which there is no progressive increase in the signs and symptoms, interruption is not necessarily indicated. Atrial heart disease can be successfully managed in some cases; the decision as to which patients can tolerate pregnancy being based upon the age of the patient, the amount of cardiac hypertrophy, the past or present congestive heart failure, and the mechanism of the heart beat. Cardiac hypertrophy should be considered evidence of severe damage and of much greater significance than the valvular lesion itself. Congestive heart failure of a progressive nature is considered to be a clear-cut indication for the interruption of pregnancy. If there has been a history of congestive heart failure in the past only with the most careful observation should the pregnancy be carried. Severe and intractable disturbances of the mechanism of the heart beat likewise may require therapeutic abortion as does the onset of acute rheumatic heart disease or subacute bacteriocarditis.

Following these two articles is a round table discussion at which a number of questions were an-

swered by the discussants. In general it was agreed that with nearly every disease individual attention should be given each patient and no over-all rule can be made to cover any disease. Both incest and rape were believed to be adequate causes for therapeutic abortion. The question of therapeutic abortion when the mother has had German measles early in pregnancy was raised. It was believed that there was insufficient evidence at this time to indicate interruption in all cases. Hyperthyroidism should be treated as if the patient were not pregnant. Recurrent toxemia of pregnancy likewise was not believed to be an indication for therapeutic abortion unless advanced cardiac or renal damage was present. In the presence of Rh incompatibility with repeated loss of the fetus, the discussants favor complete blood studies in an effort to determine whether or not the husband was heterozygous or homozygous. The question should then be referred to one of the experts on blood groups for determination as to whether or not interruption of pregnancy is advisable in that individual case. The discussion was summarized and the importance of careful medical care was stressed over that of therapeutic abortion not only because of the dangers of the latter but also because of the tremendous loss of fetal life.

JAMES J. DONNELLY, M.D.

Therapeutic Abortion: Surgical Considerations.
SAMUEL C. HANLEY / *J Am M Ass* 948, 37 33

This article is a portion of a round table discussion on the indications and problems associated with therapeutic abortion. Emergency operations, such as those for acute appendicitis and intestinal obstruction, should be performed immediately even if there is some risk of causing abortion. Other surgical problems, however, such as hemorrhoids and varicose veins, can be postponed until the pregnancy is terminated normally. Under no condition in either group is therapeutic abortion justifiable. In cancer of the breast there is no evidence to indicate that continuation of pregnancy will alter the growth behavior of the malignancy. Therefore the patient should be treated as if she were not pregnant and the pregnancy not disturbed. However, it would seem wise to let the patient not to undertake further pregnancies for at least 4 or 5 years, and preferably not at all, and not to attempt to nurse her infant with the remaining breast.

appear normal by pyelography. Detailed analysis of the collected and reported cases is presented.

ROBERT O. BRADLEY, M.D.

Renal Tuberculosis. JAMES C. MCCLELLAND, KENNETH H. DAVIS, AND ERIC MAMMO. *J. Urol.* Balt. 1945, 59, 795.

The authors have had an opportunity to supervise personally 400 cases of genitourinary tuberculosis. This article states briefly the clinical and pathological findings in the kidneys removed at operation together with those studied at autopsy. Nephrectomy was carried out in 57 of these patients whose symptoms varied, and the pyelographic changes varied from no change to marked cavitation of the parenchyma. Autopsy was done in 40 of these cases. The lesions varied from tiny ulceral cavernous lesions to complete autonephrectomy. Grouping together the surgical and autopsy specimens provided an opportunity to make gross and microscopic studies of 705 tuberculous kidneys.

In the review of the pathology the outstanding lesions seen were those of progressive tuberculous involvement and destruction of one or both kidneys. The lesions may be grouped into three main categories: (1) the early solitary or multiple caseous lesions; (2) intermediate ulcerocaseous lesions with single or multiple cavitation; and (3) the late tuberculous pyonephrosis. The entire series presented 3 autonephrectomies, 13 pyonephroses, 28 ulcerocaseous lesions with cavitation, 7 solitary or multiple caseous nodular lesions, 6 of the very early ulcerocaseous type of lesion without cavitation, and 3 cases of very early single caseous foci involving the tip of a single papilla.

This study revealed a composite picture of the course of renal tuberculosis from the tiny early caseous lesion through succeeding stages of progressive involvement and destruction of the kidney with cavitation going on to tuberculous pyonephrosis and ultimately in some instances, terminating in autonephrectomy.

The authors believe that the initial lesions were of hematogenous origin and consisted of microscopic foci of typical tuberculous granulomatous cellular reaction. At that stage they probably presented no clinical or laboratory manifestations sufficient to attract the attention of the urologist. They progressed to a later stage with caseation and destruction of kidney parenchyma and the presence in the urine of pus cells and bacilli without attending clinical symptoms. It is conceivable that such early lesions might have healed by scar formation but the fate of the lesions in this series appears to have been one of progressive evolution to stages in which the possibility of healing did not exist. No healed tuberculous foci were demonstrated in the material examined, and in the final analysis, one must conclude that if healing does not take place during the initial cellular phase of the tuberculous process, the subsequent course will be that of progressive involvement of one or both kidneys to the state in which renal

function becomes grossly impaired, and results in a state of uremia and death.

Correlation of the clinical information given by symptoms, x-ray findings and the pathological picture revealed that the clinical findings could not be depended upon to give an accurate picture of the extent of the pathological process. Kidney function tests were made but were found to have little value either in revealing the extent of damage or life expectancy.

These sanatorium patients had routine cultures of their urines, which made it possible to discover renal tuberculosis in its early asymptomatic stage before the appearance of distressing tuberculous cystitis. In cases in which tubercle bacilli are demonstrated in the bladder urine by culture, complete urological studies are carried out including catheterization of the ureters and retrograde pyelography. If the ureteral specimen is positive and the pelvic outline shows cavitation, the kidney is removed even in the absence of bladder symptoms. If the pyelogram is normal a repeat cystoscopic examination is made and ureteral specimens are once more obtained for culture. If the second culture is positive for pus and acid fast bacilli, nephrectomy is recommended. It is believed that the patient is suffering from clinical renal tuberculosis with an ulcerative lesion in communication with the kidney pelvis in spite of the normal pyelogram. A tuberculous pyonephrosis is removed if it is causing fever even though there may be an earlier stage of tuberculosis in the opposite kidney. This is the only instance in which bilateral renal tuberculosis is treated by operation.

The authors conclude that there were no areas of healing found in the surgical and autopsy kidneys examined in this series, and that clinical renal tuberculosis is treated by nephrectomy as soon as a confirmed diagnosis is made even before pyelographic evidence of a cavity is found and before bladder symptoms occur.

ROBERT O. BRADLEY, M.D.

Aneurysm of the Renal Artery (*Aneurisma de la arteria renal*). PEDRO MONTEIRA BERRAN and ALBERTO HALLAC. *Rev. argent. urol.* 1947, 6, 53.

The authors' patient, a 15 year old girl, had always felt a certain amount of pain in the lumbar region. About a month previously the pain became worse and now radiated to the epigastric region. Upon examination the only findings were bad teeth and pain on pressure over the right ureter and kidney pelvis. The right kidney seemed to be enlarged and was somewhat sensitive to palpation. The retrograde pyelogram revealed a renal pelvis with an odd rectilinear medial border and absence of the middle calyx, this portion being represented by a small rounded protrusion on the shadow border. In the middle of the pelvic shadow was a light area of rounded contour and about the size of a walnut. The kidney was approached through the lumbar region and the walnut-sized aneurysmal mass was disclosed beneath the renal vein but on the anterior aspect of the renal pelvis. The mass was surrounded by numerous fine

inasmuch as both the growth-producing factors and the sex stimulating factors are centered in this gland. The proponents of this theory believe that pituitary dysfunction could cause the dwarfism and that secondly an autonomic center in the adjacent dien cephalon could cause urinary tract abnormalities in which there was no mechanical block. This would allow the chemical imbalance of the calcium and phosphorus metabolisms to result finally in a secondary parathyroid hyperplasia. However, the author states that in the case presented, the primary lesion was in the kidney and the rickets did not develop until 3 1/2 years later.

There is at present a tendency to try to explain the syndrome on the basis of acidosis inasmuch as osseous lesions of a much milder type can almost regularly be found in adult cases of prolonged renal insufficiency. None of these theories in themselves will explain all the findings of this syndrome.

The disease occurs in childhood and early adulthood and both sexes are equally affected. The symptoms are failure to grow, bony deformity, enlargement of the epiphyses, the presence of Harrison's groove, rachitic rosary, difficulty in walking, increased weakness, polydipsia, polyuria and symptoms of uremia, and evidence of delayed sexual development. Kidney function tests will show impairment of renal function. The blood phosphorus is nearly always elevated, which is believed to be due to the inability of the kidneys to secrete the waste endogenous phosphates. The blood calcium may be below normal or even increased. Most cases terminate in uremia. However, no 2 cases are alike and

Howard stated: "This is a disease of contradictions."

ROBERT O. REARDEN, M.D.

Adenocarcinoma and Tuberculosis of the Same Kidney HAROLD A. NEUBERG and WALTER WALTERS. *J Urol Balt* 94:5 59, 2.

A review of the literature and especially of isolated cases presented since the last general review of the literature on the subject together with a summary of 7 cases of combined tuberculosis and hypernephroma of the same kidney is presented. All but one of the 7 patients whose cases are reported were males. The ages varied from 38 to 63 years; the average age being 50.1 years.

Surgical considerations and removal of the lesions presented primarily the same problems as those encountered in nephrectomy for hypernephroma or for tuberculosis depending on which disease the combination found in this series most nearly resembled. The incisions used were posterolumbar, because it has been the consensus at the Mayo Clinic that most tumors of the kidney are accessible by this approach as by the transperitoneal approach advocated by some authors for the removal of large renal tumors. The adequacy of the posterolumbar approach is illustrated by the relative ease with which the large tumor in 1 case was removed. This tumor was a cystic mass 24 by 16 by 6 cm. from which some 2,500 c.c. of fluid were aspirated by trocar.

Nephrectomy in all cases was carried out in the usual manner, the attempt being made to isolate and clamp the renal vein as early in the operative procedure as possible. When the lesion resembled a frankly tuberculous condition and there was concomitant ureteritis partial ureterectomy also was done.

Pathologically the malignant processes were mostly of low grade (Broders' method) with a preponderance of grade 1 lesions. This range of grade is in keeping with the observations of McDonald and Priestley who showed that the majority of hypernephromas removed at the Clinic are of the lower grades (1 and 2) based on the Broders' method of classification.

The size of the tumors varied greatly from the smallest discrete hypernephroid lesion of 3 mm. to the largest tumor measuring 24 by 16 by 16 cm. in which the malignant process and the tuberculosis were intermingled indiscriminately.

It is also of interest to observe that most of the lesions contained discrete areas of hypernephroma in a tuberculous kidney or small portions of tuberculosis in a kidney mass composed chiefly of neoplastic tissue, and only in 1 case was there apparent intermingling of tuberculosis and carcinoma.

The length of survival of the patients after operation is in close agreement with the general prognostic tables suggested by McDonald and Priestley in respect to hypernephromas.

It is noted that the diagnosis is directly related to that portion of the combined disease which predominates. In no recorded instance has the complete diagnosis been made preoperatively.

The prognosis probably is no better for the combined disease than it is for hypernephroma alone.

Ureterotuberculous Anastomosis (Ureterotuberculous-anastomosis) E. CARY WO., L. B. ORTLE, and J. F. TORR. *Ann Surg* 94:17 319.

Brief case summaries of 9 patients with vesicular blastoma are presented. The patients ranged in age from 43 to 68 years. The presenting symptoms included hematuria, pyeluria, cystitis, and dysuria. Cystoscopic examination revealed varying degrees of bladder involvement. Bilateral ureterotuberculous anastomosis was performed as a single stage operation in 3 patients and as a two stage operation in 3. One patient the only operative mortality in the series died in surgical shock within 24 hours after the right ureter had been transplanted. Follow-up pyelograms taken from 1 to 11 months after operation on 4 of the patients showed unilateral or bilateral ureteropelvic dilatation or diminished or absent renal function.

Preoperative preparation of the patients began 4 days prior to operation with the administration of a purge. This was followed by daily cleansing enemas and a tablespoonful of mineral oil by mouth each evening at bedtime.

To effect sterilization of the bowel sulfasuxidine or sulfaguanidine was given daily for 4 days prior to

GENTOURINARY SURGERY

operation in a dosage of 0.25 gr. per kilogram of body weight, divided into 6 or 8 doses. A few minutes before the patient went to the operating room an enema of rivanol was given him and he was brought to the operating table with the rectal catheter *in situ*.

Except in cases in which contraindications existed spinal anesthesia was used.

Postoperative precautionary measures consisted of the maintenance of hydration and homeostasis and the administration of penicillin and sulfasuxidine for their combined effect upon the intestine and the urinary system.

In the immediate postoperative period great care was exercised to prevent paralytic ileus. For this purpose hypertonic saline solution was introduced into the intestine by way of the rectal catheter. The latter which was left *in situ* from immediately prior to operation also served the purpose of maintaining a ready exit for flatus and urine from the lower intestinal segment. Insistence was placed above all on the early passing of a Miller Abbott tube. This insured a more tranquil postoperative period, eliminated abdominal distention and prevented traction on the sutures.

The operative results are divided into three categories: immediate, intermediate and late. The immediate period encompassed the time from operation until the patient abandoned his bed; the intermediate from that time until a year after surgical intervention; and the late after one year.

In the immediate period there were no accidents related to disruption of the anastomosis or the development of urinary or intestinal fistulas. Healing per primam was observed but no peritoneal reactions were noted. Immediate proctitis was avoided by careful attention to the rectal tube which was kept *in situ* for 5 or 6 days and reinserted if symptoms of proctitis presented.

Other than proctitis there were no overt sequelae in the intermediate period. During this time emphasis was placed upon the patient's return to a normal social existence.

In the late period that is, later than a year after surgical intervention the patients who had been followed up through the three periods began to feel the consequences of an unnatural function. Infection which possibly had been present but well tolerated before appeared as a crisis. Large dilatations of the ureters, pelvis and calyces, and rapid decadence of renal function occurred. Urinary systems which before had functioned perfectly began to show signs of loss of their secretory and excretory functions.

HAROLD W. BISHOP, M.D.

BLADDER, URETHRA AND PENIS

Construction of Terminal Urethra in Hypospadias.
JOSEPH H. KIEFER, J. Urol., Balt. 1947 59: 1160.

A procedure is presented in which the terminal portion of the reconstructed urethra is formed from a foreskin flap and brought through a tunnel to the

Fig. 1. A, Showing how loose skin is pulled distally to measure how much is needed to reach the dimple. B, Flap outlined. C, Flap formed into a tube and tunnel made. D, Tube drawn into place and sutured.

dimple in the glans. The penis is straightened after a complete encircling incision is made, as advocated by Nesbit. This usually provides considerable excess of skin on the ventral surface. The excess varies from 1 to 5, or more centimeters according to the amount of the urethral defect and the length of the foreskin. The amount of excess is measured by stretching the penis to its full length and measuring the amount that will be required to reach from the bypospadiac meatus to the dimple on the glans. The excess of skin which remains is measured and this measurement is the length of the tunnel.

A skin flap is constructed (Fig. 1). This flap must be the same width in millimeters as the caliber of the desired urethra in numbers of the French scale. The tunnel is made by incising the dimple through the tissue of the glans and continuing under the remaining skin (Fig. 2). Bleeding may be profuse at first but is easily controlled by pressure or the use of clotting agents such as thrombin solution. The flap which has been raised is then formed into a tube around a catheter by using a continuous subcuticular stainless steel suture. The tube so formed is then drawn through the tunnel and the edges are stitched to the adjacent edges of the glans at the dimple. The edges of the skin flap incision fall together quite naturally and are sutured with interrupted cotton or plastic silk worm gut. The catheter is removed and

Fig. E, (Kleiser) Showing how a complete procedure may be done at one operation if the defect is not great. F, When the defect is large, the method may be combined with the Duplay procedure. Only the distal portion of the new urethra can be brought through the tunnel. The large bare area is covered by a scrotal skin flap.

a pressure dressing is applied. Usually at this time a pedicled flap is raised on the scrotum for use at the final stage. When this is healed the patient has the terminal 3 or more centimeters of his urethra, and the intervening segment is constructed at the final operation by the method of Duplay. The bare area is covered by a scrotal flap without any tension or superposition of suture lines.

The portion of the urethra so constructed can easily be sondeed or dilated when necessary.

The advantages of the method are that healing of the terminal portion is excellent and breakdown unlikely. It gives a normal appearing penis with the meatus in its proper position. The functional result is also excellent as the stream is normal and does not spray.

FREDERICK A. LLOYD, M.D.

GENITAL ORGANS

The Prostatectomy of Terence Millin—The Operation of the Future (Prostatectomie de Terence Millin, opération d'avenir) H. DUVERNOY *Bardes* 1947 No. 3. 33.

The author mentions first the advantages and shortcomings of the perineal and suprapubic methods of prostatectomy. The perineal method as practiced in the United States and Germany is an anatomical operation with perfect hemostasis and with less shock than the method of Freyer. Nevertheless, it is a deli-

cate and occasionally difficult operation with certain dangers to the rectum and the possibility of fatal formation.

The Freyer operation is simple and rapid but has the disadvantage of a transvesical approach with two wounds in the bladder. It proceeds in an infected medium, and is occasionally followed by shock and a painful postoperative course which requires close medical supervision.

There are two modifications of Freyer's operation, one by Fabre, with enucleation, complete hemostasis of the prostatic bed, and primary closure of the bladder with urethral catheter drainage. The other modification was made by Darget, with hemostasis secured by a balloon catheter and with perineal drainage and primary closure of the bladder. In contradistinction the operation (retropubic) by Terence Millin permits a direct approach by the shortest route without danger to the adjacent organs, such as the rectum and external sphincter and no opening of the bladder. Due to the advancement made with sulfonamides and antibiotics, the danger from cellulitis in the space of Retzius is minimal. Hemorrhage can be controlled by electrocoagulation.

The author has operated on 5 patients. 3 were completely cured on the sixth postoperative day. 2 had a fistula, one closing on the fourteenth day and 1 patient had complete retention of urine necessitating cystostomy. The author describes Millin's surgical procedure in detail with diagrammatic illustrations. The following highlights of his description are noted.

After the opening in the midline is made retropubically and a Harris automatic retractor is in place two pads support each side of the prostate and hemostasis is achieved by electrofulguration. The capsule is incised transversely. Hemorrhage is controlled by aspiration. Enucleation is started laterally with scissors and continued digitally. Sharp transection of the urethra at the prostatic apex precedes the enucleation and sharp transection at the vesical neck completes it. Hemostasis of the prostatic arteries at 3 and 9 o'clock is done by fulguration. The vesical neck is dilated with a spreader and wedge-shaped resection of the posterior lip. A Nelaton catheter with two eyes is inserted and the capsule is closed with interrupted sutures. Sulfanilamide powder is applied, and except for the drain the wound is completely closed. One hundred cubic centimeters of sterile water are injected into the bladder and bilateral vasectomy is done. No postoperative irrigation of the bladder is necessary. The catheter and drains are removed after 3 days.

The blood loss during the operations varies from 100 to 400 c.c. No postoperative hemorrhage was observed. The urine became clear in 24 hours. This perfect hemostasis does away with packing and postoperative pain.

The asepsis of the operation is important. The bladder itself is hardly opened because of the competence of the sphincter at the vesical neck. This is best demonstrated by the injection of 100 c.c. of

GENITOURINARY SURGERY

water which are retained in the bladder. The post operative course is therefore afebrile. In cases with severe infections prior to operation a two-way continuous irrigation, sulfonamides and antibiotics will prepare a favorable field for intervention.

The urinary stream flows through the natural route and therefore fistula formation is reduced as compared with other operations.

There is no shock and the operation can be executed within 20 to 30 minutes. The postoperative comfort of the patient is greater than that following other methods. From a practical consideration hospitalization is shortened to only about 12 days. Because of all the advantages the author believes that once an adenoma of the prostate is present this operation can be recommended to the patient prior to the onset of dysuria, polyuria, or the development of residual urine. This will lead to a broader indication and to early prostatectomy.

ERNEST BOSS, M.D.

Rationale and Results in Retropubic Prostatectomy
OWSLEY GRANT and ROBERT LICHT, JR. *Ann. Surg.* 1948 127 1010.

Three methods of prostatectomy have been recognized up to recent months. The suprapubic operation has the highest mortality; it is a blind procedure offers no positive blematostatic control and does not make possible the removal of an operable carcinoma. Transurethral resection is a procedure well adapted to small glands, median bars, and the inoperable obstruction of carcinoma. Prolonged pyuria, urethral stricture and inadequate resection are the unfavorable aspects of this operation. Perineal removal is a truly surgical operation which offers positive blematostatic control, removal of carcinoma radically, stasis, the ability to remove carcinomas, fistulas and in low morbidity and low shock. Fistulas and incontinence are the unpleasant sequelae.

In the hands of the authors who have performed the largest series of retropubic prostatectomies in

Fig. 2. A. Incision in the capsule between the ligated vessels. B. Division of the urethra at the apex within the prostatic capsule.

the United States this operation has proved to be the procedure of choice for the removal of large glands, both benign and malignant. The transverse glands, both benign and malignant. The space skin and fascial incision is preferred and the space of Retzius is swept clean of fat. The vessels in the prostatic sheath are sutured transversely. A long pair of Mayo scissors is introduced into this wound and the adenoma loosened from its bed. The urethra is cut at the apex of the gland. The adenoma is then enucleated from the apex toward the bladder. When

Fig. 3. A. Skin incision. B. Exposure of vessels in adipose tissue covering the prostatic capsule.

Fig. 4. The enucleated gland delivered being trimmed from the vesical neck.

Fig. 4 (Grant and Lich) Ligation of the prostatic arteries

the enucleation has reached the vesical neck, the gland is lifted into the wound and the cuff of bladder attached to it is severed. The prostatic arteries are seen and sut red and any remaining bleeders are fulgurated. The bladder is explored with the finger for calculus or diverticuli. The prostatic fossa is inspected for nodules or tags. A catheter is then introduced into the bladder and the incision in the capsule is closed with a running suture. A rubber tissue drain is laid and the wound closed in the routine manner. The catheter and drain are usually removed on the third day.

In radical retropubic prostatectomy the steps are the same up to the point of incision into the capsule.

Fig. 5 A Closure of the prostatic capsule over retention catheter B, Skin closure with cigarette drain.

The puboprostatic ligaments are severed and the urethra is cut across. The gland with its intact capsule is then turned toward the bladder which causes separation from the rectum and allows the seminal vesicles to come into view. The gland is then cut free from the vesical neck, and the seminal vesicles are removed with the rest of the specimen. Anastomosis of the bladder neck to the cut stump of the urethra after hemostasis, completes the procedure.

The authors are well pleased with the results to date. Transfusion has seldom been necessary and there has been no case of incontinence or fistula. Most of the patients left the hospital on the eighth postoperative day. JOSEPH E. MAURER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES TENDONS ETC

Renal Osteodystrophy in the Adult (Osteodistrofia renal en el adulto) JOSE VALLS, FRANK SCHAIKOWITZ and CARLOS DELBOS. *Rev orlop traumatol* B Air 1947 17 8.

Two cases of renal osteodystrophy are reported with a detailed analysis of the clinical symptoms course roentgenologic, histologic and chemical studies, bone involvement and anatomicopathologic examinations

Chronic renal insufficiency and uremia normal serum calcium hyperphosphatemia and acidosis were observed in both patients. The urinary calcium was low but the stool calcium was high. Osteitis fibrosa characterized the bony lesions of one patient with trabecular sclerosis not unlike Paget's disease, whereas the other case revealed only bony atrophy of the vertebrae and ulna.

Remission of the renal lesion was associated with a normal phosphatemia and increase of bone formations, but bony lesions, acidosis, and high calcium content in the stool followed long standing renal insufficiency

The relationship of parathyroid hyperplasia to the disease as found in the literature was discussed although the parathyroid glands in the 2 patients studied could not be examined. Other features of the disease as outlined in the literature were summarized

STEPHEN A ZIMMAN M.D

Osteoarthritis of the Cervicodorsal Spine (Radiculitis) Stimulating Coronary Artery Disease. DAVIS and MAX RIVRO *N England J M* 1948 338 857

The authors analyze the clinical and roentgenologic findings in 43 patients complaining of attacks of substernal or precordial pain of nerve-root origin (radiculitis). The location character, and radiation of the pain closely simulated these findings in disease of the coronary artery.

The diagnosis of radiculitis was based on at least two of the following factors attacks of pain in bed with change in body positions and on coughing sneezing or straining over the dorsal spine and n attacks by pressure over the dorsal spine

In addition to the generally recognized features of radiculitis of the cervicodorsal spine, particular attention is called to the occurrence of a peculiar respiratory distress of radicular origin that may easily be mistaken for a manifestation of heart disease. The value of parasternal tenderness as a sign of dorsal root irritation is also emphasized

The patients in addition to irritation of the dorsal nerve root showed a high incidence of symptoms and signs of cervical radiculitis such as pain in the

shoulder girdle suboccipital headaches vertigo muscle spasm tenderness, and limitation of neck rotation

Roentgenological examination of the dorsal and cervical spine showed a high incidence of postural and osteoarthritic changes. The changes in the cervical spine may be summarized as follows disk narrowing 18 cases anterior osteophytes 39 cases posterior osteophytes 23 cases scoliosis 31 cases intervertebral joints 11 cases increased lordosis 5 cases straightening 23 cases osteoporosis 22 cases. In the kyphosis 1 case and osteoporosis 22 cases. In the dorsal spine there was disk narrowing in 7 cases anterior osteophytes in 39, posterior osteophytes in 4 and scoliosis in 30

The roentgenologic findings demonstrate the location nature and extent of the osteoarthritic changes in the spine and are of some value to the clinician when the symptoms are of short duration, the attacks cannot be reproduced or the radicular characteristics are not clear

The recognition of radiculitis and its differential diagnosis from coronary disease of the artery are of practical importance in therapy and prognosis.

Symmetrical Equal Bilateral Epiphyseal Separation of the Distal Radial Epiphysis (Distacco bilaterale e simmetricamente uguale dell'epifisi radiale inferiore) PASQUALE PICARA *Ann Ist osp Aquila* 1946-47 1 257

The author reports a single case of bilateral separation of the distal radial epiphysis which was probably unique because of the fact that the separation was of the same degree on both sides. Superimposition of the films showed the identical displacement. The patient was a boy 16 years of age, who while sawing a limb off a tree fell and struck both arms against the ground. Under local anesthesia the posterior radial displacement of the epiphyseal fragments was reduced and the arms were placed in circular plaster casts.

The author discusses the hibiography terminal ogy pathologic changes and treatment of this condition

CARLO SCUDERI M.D

Low Radioulnar Dyschondroplasia or Madelung's Disease (Dischondroplasia radio-cubital inferior o enfermedad de Madelung) ALBERTO INCLAN COSTA *Cir orlop traumatol* Habana, 1946 13 68.

Three cases of Madelung's disease in which surgical procedure gave satisfactory results are presented. All the patients were young females, 2 of whom had serious endocrine imbalance. There was no history of infection or injury however 1 patient used considerable force while practicing on the piano

The pathogenesis suggests numerous theories such as the mechanical traumatic, muscular contraction

following infection endocrine and hereditary. Because the symptoms are more objective than subjective, and are insidious in character. It is believed that the deformity is best studied by means of roentgenography.

Because of the progressive nature of the disease conservative methods of treatment are not satisfactory.

Surgical intervention consisted of corrective osteotomy of the radial incavation, shortening of the ulna with raising of the head of the ulna, and transplantation of the bony fragments obtained to the lower and inner portion of the osteotomized radius. A second surgical procedure has been required in these cases.

STEPHEN A. ZICKMAN, M.D.

Osteochondritis Dissecans of the Hip (Osteochondritis dissecans de la cadera) JOSE VALLE and DOMINGO T. MÓSCOLA. *Rev. chir. y traumat.* B. A., 947 7 47

The authors discuss 5 cases of osteochondritis dissecans of the hip. They believe that trauma has little to do with producing the lesions because they were unable to find in the literature any indisputable evidence of direct relationship. Furthermore, approximately 30 per cent of the cases are bilateral, and not infrequently Perthes disease coexists. Certainly none of the 5 patients was exposed to sufficient trauma to bring on the lesion.

Clinically the process may be confused with chronic rheumatism. There are no specific features of the disease. Most cases present a slow and painful course. Roentgen examination reveals the only distinctive characteristic the lesion being practically always found in the upper lateral portion of the head of the femur.

Treatment utilizes physical therapy immobilization simple sequestration arthroplasty and arthrodesis.

Three of the authors' patients were operated upon, the first developed arthritis deformans, the second recovered completely after 5 years, and the third has been operated upon too recently to permit appraisal of the results. A fourth patient, treated conservatively, is well after 7 5 years.

STEPHEN A. ZICKMAN, M.D.

Popliteal Hygromas (Higromas Popliteos) LEONARD LUTS FERNSTEDT. *Cirugía*, 947 4

The majority of tumors which develop in the popliteal space are hygromas of the serous sac of the semimembranosus and internal hamstring muscles (popliteal cysts, cysts of Baker). These tumors appear at the level of the crease behind the knee and, after they have expanded into the lower portion of the popliteal space, expand upward over the posterior area of the thigh.

These cysts are located medially and never in the midline a fact which distinguishes them from synovial herniations. Their surfaces are smooth and at times indented when they increase in size. They are tense and elastic.

The skin which covers these popliteal hygromas is not modified except in the presence of very large cysts in children when it becomes thin and transparent. The cysts are not painful and are usually found inadvertently by the patient or in the course of routine physical examination.

The differential diagnosis is between aneurysms of the popliteal vessels, lipomas, and synovial hernias.

The most important of these is the first and this is easily eliminated by the absence of palpable fremitus and bruit. By puncture of the cyst with a needle of large caliber a thick syrupy pale yellow liquid can be obtained. The use of a needle which is too small often leads to an erroneous conclusion.

Radiological examination of the knee is almost always negative. It is not rare however to see signs of arthritis in older patients. Filling of the cysts with lipiodol or air will define the limits of the sac; however this is not necessary to establish the diagnosis.

The greatest incidence of popliteal hygromas is in males over 45 years of age and in boys less than 12 years of age. In the older age group there is a tendency of the cysts to appear abruptly.

Radical treatment consists of complete surgical excision of the hygroma. In older persons one may resort to palliative evacuation of the cyst by puncture and continuous application of a compression bandage. The use of injections of irritating liquids is contraindicated.

The incision of choice is transverse and is made at the equator of the tumefaction. When the development of the hygroma is such that it extends downward in the popliteal space the transverse incision is placed at the level of the intertarsal line. The surgical draping of the leg should be so arranged that the leg may be flexed during operation without danger to asepsis.

Flexion of the extremity is necessary at certain times during the operation in order to relax the muscles and tendons which are at their maximum tension in the position of extension.

The anesthesia of choice is local.

After incision of the skin a small subcutaneous dissection is made to expose the aponeurotic plane clearly. An incision is then made in the fascia of the exact size of the skin incision, since it is this tense connective tissue which adds to the difficulties of exposure and dissection of the deepest portion of the hygroma. Upon sectioning the aponeurotic plane one will encounter the external saphenous vein at the medial end of the incision. This may be retracted medially if the hygroma is of moderate size, or sectioned between two ligatures if the hygroma is large.

Immediately beneath the aponeurotic plane one encounters the hygroma. Separation of the tumor is begun along the lateral border and continued at the inferior pole. After this the medial border is separated. Here the hygroma is intimately adherent to the tendon of the semimembranosus; however it may be separated by careful dissection.

In general when the cyst is dissected one observes that the wall of the tumor is adjacent to, and adheres

SURGERY OF THE BONES JOINTS MUSCLES TENDONS

the facial planes and tendons is covered with bone tissue, and is easily separated from the muscular planes.

Almost invariably, upon separation of the hyponoma from the covering of the medial hamstring tendons, it is opened. The opening and evacuation of the contents favor final dissection.

The separation of the cyst is continued superiorly and deeply, the operator being guided by the tendon fibers of the superior pole of the tendinous pneumatic sac. Separation of the cyst at its uppermost border almost invariably leaves a small foramen in the synovial covering of the cartilage of the medial condyle of the femur. This does not signify pre-existence of a communicating foramen.

The operation is completed by careful suture of the fascial layer and skin. There are no special post-operative precautions.

SURGERY OF THE BONES, JOINTS MUSCLES, TENDONS, ETC.

The Bridging of Bone Defects. A. GIBSON and B. LOANMAN. *J Bone Surg* 1948 30-A 381

The authors report the methods used and the results obtained in bone-grafting operations for defects and nonunion of the bones of the extremities on 105 patients at Deer Lodge Hospital, Winnipeg, Canada. All the patients operated upon were good surgical risks. In 85 per cent of the cases the injury was caused by a gunshot wound. Accidents of various types many involving motorcycles were responsible for the remainder. All but a few of the injuries occurred overseas and consequently there was an interval of several months between the time of injury and admission to the hospital.

Early in the series the cortical inlay or onlay graft with some cancellous bone from the upper end of the tibia, was used in almost every case. Later when more had been learned about iliac cancellous bone, this type of graft was used more frequently either by itself or in combination with other methods. The results obtained from the various methods are tabulated in the article.

Union occurred in 93 cases. Penicillin was used routinely after every operation and no graft was lost or failed to unite because of primary wound infection. In 84 patients, or 80 per cent of the cases, the first graft was successful. The cortical onlay graft was used 29 times in 27 patients and union resulted in 23 patients, or 79 per cent of the cases. The cortical inlay graft was used 27 times in 23 patients and union resulted in 21, or 85 per cent of the cases. Cancellous bone alone was used 23 times in 23 cases to fill gaps, or to promote union, or 87 per cent of the cases. Combined with a metal plate, it was used 13 times on 13 patients with union in 9, or 69 per cent of the cases. It was used 9 times in 9 complete defects of the shaft of the long bones and fused

with the shaft in 7 patients or 78 per cent of the cases. In 12 cases cancellous bone alone was used to fill infected bone cavities with discharging sinuses. Wound healing occurred in 9 cases.

It was concluded that for ununited fractures, or for short gaps in the shaft of the radius, ulna, humerus, and femur the cortical onlay graft fixed with vitallium or stainless steel screws is the most efficient. Cancellous bone should be placed between the fragments and around the cortical graft. In the upper end of the shaft of the femur it should be combined with a metal plate or with a second onlay graft. In the ulna, if the size of the gap is 3.8 cm. or more, or if the fragments are difficult to control, a Lane plate used with the cortical onlay graft, may prevent absorption and fracture of the graft.

The sliding inlay cortical graft gives excellent results for ununited fractures, or defects of 5 cm. or less in the shaft of the tibia.

Cancellous bone alone will bridge a bone defect or promote union in ununited fractures in a high percentage of cases. However, before function can be allowed longer immobilization must be expected than if a cortical plate union may be slightly less certain but plaster immobilization is shorter. Its most practical use is in filling incomplete defects in the shafts of the long bones.

Infected bone cavities can be filled with cancellous bone and a high proportion of successful results can be anticipated if full thickness skin can be closed over the cavity and graft. This method may prove useful in the treatment of osteomyelitis of the tarsal bones.

FRACTURES AND DISLOCATIONS

Primary Closure of Compound Fracture Wounds. With Immediate Internal Fixation. Immediate Skin Graft, and Compression Dressings. ARTHUR G. DAVIS. *J Bone Surg* 1948 30-A 405

A review of 50 consecutive cases of compound fracture was presented in 1942, treatment of which consisted of immediate débridement, metallic internal fixation, skin grafting and compression dressings.

The present report is based upon a series of 150 consecutive cases of compound fracture observed during the 12 year period from 1936 through 1946. During the first 5 years when neither sulfonamides nor penicillin were available, 28 patients were treated. In the next 4 years 83 patients were treated with sulfonamides. In the final 2 years, 39 patients were treated parenterally with penicillin, in addition to the 3 cases a sulfonamide was dusted into the wound. During the last 5 years a blood bank has facilitated the generous use of transfusions and a high protein diet has been prescribed.

Except for modifications attending the advent of the newer bacteriostatic agents the blood bank, and the high protein diet the program of treatment described in 1942 has undergone no important change.

Greater experience however has taught the value of a more radical excision of questionable skin. With the adoption of this policy it has been possible to reduce the incidence of sloughing of the wound edges and subsequent infection. Improved techniques in the transfer of split grafts together with the use of the Padgett dermatome have facilitated the grafting of large denuded areas.

Because of variables involved in the individual case it is extremely difficult to evaluate the merits of any single approach to the treatment of compound fractures. It is sometimes impossible and frequently inadvisable to do combined immediate treatment of bony débridement, internal fixation and closure. Six case reports are given in which different approaches have been used in accordance with the immediate requirements of the individual patients.

In respect to wound healing, bony union, prompt restoration of function and the salvaging of extremities the results have been superior to those obtained by previous methods. Improved results are attributed first to the compression dressing second to immediate coverage of the surface defect with skin or split skin graft and third to immediate or delayed internal hardware reduction with metallic fixation when indicated.

The hazard of primary suture is greatly reduced by penicillin and the availability of whole blood. If along by first intention has been more frequent since the adoption of more radical excision of partly or wholly devascularized skin flaps. Temporary removal of the tourniquet has been found to be the only dependable aid in evaluating the vitality of the skin.

A thorough knowledge of and easiness in skin plastic surgery are important for selection of the optimum covering of the individual skin defect. Preference is given to the approximation of relaxed flaps whenever possible. Defects caused by relaxing incisions are covered immediately or later by split grafts.

Evaluation of the end results of compound fractures is facilitated by photographs of the external wound made at the time of the usual admission roentgenogram, and repeated 2 weeks later at the time of the first dressing.

An attempt has been made to evaluate the therapeutic indications in each case on admission and to determine the factors which require immediate treatment. Definitive fracture treatment should frequently be postponed. It is usually advantageous to carry out simultaneously the treatment of shock and careful débridement followed immediately by closure of the skin and the application of a compression dressing.

RUDOLPH S. REICH, M.D.

The Management of Compound Dislocations.
JAMES K. STACE and PAUL MILLIGAN. *Q. Bull. Northwest Univ. Med. School* 1948 31: 66.

The authors have reviewed the literature of compound joint injuries and describe the method of

treatment of compound dislocations as exemplified in their 12 cases.

Compound injuries to joints are of course emergencies and treatment is carried out as early as possible in the operating room under general anesthesia and with a tourniquet. If a state of shock exists the treatment for this may be carried out concurrently.

The wound and protruding bone ends are covered with sterile gauze. The skin area is shaved and thoroughly cleansed with soap and water and a skin antiseptic is applied up to the wound edge. The extremity is then draped and the wound débrided. It is usually necessary to enlarge the wound. Tissue into which dirt has been ground must be sacrificed, and it is the inadequate or timid performance of this step in the procedure which is the most common cause of subsequent sepsis. If the bone end is dirty it is best to remove about one-eighth inch with a thin sharp osteotome. If dirt has been ground into the articular cartilage layer after layer should be shaved off with the scalpel until the uninvolved base is reached. Following this the wound is gently irrigated with saline solution and closed. It is essential that the joint be covered and thoroughly protected, even if fascia is required to make a water tight compartment. Prior to closing of the skin penicillin solution may be injected into the joint cavity. Wounds heal best if compression bandage is used and immobilization is usually obtained by means of a plaster cast.

VERNON C. TRACY, M.D.

The Magnuson Stack Procedure for Recurrent Dislocations of the Shoulder. N. J. GRANTHAM. *Surgery* 1948, 3: 704.

The theories in favor and against repair of recurrent dislocations of the shoulder are discussed. The Magnuson Stack procedure is given in detail including the operation.

Thirty-one shoulders in 30 patients were operated on by the author. Sixty per cent showed evidence of avulsion of the capsule from the glenoid rim. There have been 2 recurrences to date.

At the time the article was written 27.6 per cent of the patients had definite limitation of external rotation. The remaining 72.4 per cent had a trace or no limitation of external rotation. Abduction was limited in 5 patients. Two patients showed a loss of forward extension. Eight patients reported the presence of pain. Seventy-seven and one-half per cent had painless shoulders.

This procedure was successful in 91.6 per cent of the patients in the present series of cases, with a minimum follow-up of 1½ years.

Mechanism of Fracture of the Carpal Scaphoid.
(Mecanismo de fractura del escafoides carpiano)
HERNANDO BAL LAGO. *Rev. ortop. tra. med.* R. A. 1947 7: 66.

Direct trauma may produce fracture of the carpal scaphoid but this occurrence is apparently rare.

SURGERY OF THE BONES JOINTS MUSCLES TENDONS ORTHOPEDICS IN GENERAL

direct blow over the anatomic snuff box area or an anterior surface of the wrist may result in fracture. However, this article is concerned chiefly with fractures occurring after indirect traumatization. The fracture occurs while the hand is in flexion or at a closed angulation or while the hand is in extension or at an opened angulation.

In the latter, the hand is in hyperextension as regards the semilunar bone and the first row of carpal bones, and the second row of bones is displaced posteriorly.

The indirect trauma includes (a) avulsion of the tuberosity by ligamentous strain (b) closure of the angle in the frontal or sagittal plane (in the author's opinion there is a closure of the frontal angle instead of the sagittal angle) (c) divergent compression or compression of the body of the navicular bone and (d) torsion (this is considered an original view) and (e) opening of the sagittal angle (this is the type of fracture that usually accompanies dislocation of the lunate).

STEPHEN A. ZIEGLER, M.D.

Fatigue Fractures of the Fibula. H. JACKSON BLOOM. *J Bone Surg* 1948 30-B 366

Fatigue fractures are spontaneous fractures of seemingly normal bone. They appear to result from a summation of stresses which singly are insufficient to produce fracture.

The author reviews the literature concerning fatigue fractures of the fibula and reports several personal cases. The fractures occurred 1 1/2 inches above the tip of the malleolus in the 5 women observed by the author and at a slightly higher level in a male patient.

Repetitious activity, movement in walking, running, and skating produced the symptoms of pain, stiffness, localized tenderness and at times localized swelling. Sometimes there is slight redness and in the author and at a slightly higher level in a male patient.

Repetitious activity, movement in walking, running, and skating produced the symptoms of pain, stiffness, localized tenderness and at times localized swelling. Sometimes there is slight redness and in the author and at a slightly higher level in a male patient.

During the first 15 days or more there are no radiographic changes. In most cases but occasionally a fracture line may be evident after a week. At times there is a band of rarefaction. Callus may be observed at the end of a week in children and during the third week in adults. A dense band is often the first indication of the fracture site and almost always disappears. The diagnosis is often confused with osteomyelitis, tuberculosis, congenital syphilis, sarcoma, and myositis ossificans.

The author recommends elimination of the exciting activity and the pursuit of normal function with the aid of an elastic adhesive bandage from the metatarsal heads to the upper calf. Cases of "pseudofractures" in the upper third of the fibula have been reported by others usually occurring in soldiers, especially infantrymen. Several cases of similar fractures in the middle third of the fibula have been reported. Fatigue fractures of the fibula may be bilateral.

Acute Circulatory Failure in an Injured Limb. L. GARRERNA. *J Bone Surg* 1948 30B 280.

Sudden arrest of the circulation in a limb is a catastrophe of particular interest because apart from embolism and of vascular complications of fractures most confined to the vascular injuries of a limb and accidents after the use and abuse of tourniquets are rare.

Ischemia threatening an injured limb gives rise to the syndrome of pain, pallor, paralysis and pulselessness. It is due to arterial injury by lacerations, compressions, intramural rupture or contusion or to arterial damage with or without demonstrable local arterial injury from organic obstruction is not possible by clinical methods.

Unfortunately, complete arrest of the arterial circulation of an injured limb is seldom recognized until too late. Effective action is too often delayed. Vasodilator drugs have been disappointing. Eupaverine is probably useful. Papaverine is certainly not. Tetracetyl ammonium bromide is still on trial. It promises well as a means of paralyzing the sympathetic but it has potential dangers. Heparm and other anticoagulants may be indicated to prevent or limit thrombosis. Alkalies are of great value and should always be given as a protection against renal failure. The only other useful drugs are morphine and other sedatives which should be used freely. The suggested plan of treatment and of management is:

1. General systemic investigation of the blood pressure, blood count and coagulation time
2. Removal of all external pressure
3. Resuscitation
4. A direct attempt to relieve the obstruction in operation
5. Postoperative care

The operative procedure recommended is:

1. Manipulative reduction of the fracture if possible
2. Proximal control of the artery (unless contraindicated by time factors and by the anatomy of the collateral circulation) liberation and mobilization of the vessel repair by suture when this is necessary and possible and arterectomy only if necessary local damage
3. The provision of sympathetic block by injection or by sympathectomy
4. In the postoperative care, in addition to the alkali, penicillin should be given as a routine measure. The limb should be slung on some open form of splintage but not compressed. It should be slightly elevated and kept cold. Smoking is prohibited but alcohol may be used.
5. A vasodilator

DANIEL H. LEVINTHAL, M.D.

Acute Hematogenous Osteomyelitis. A Study of Treatment. WILLIAM NACHLAS and HERBERT R. MARKHEIM. *J Bone Surg.*, 1948, 30-A, 673.

Presently we are confronted with two diametrically opposite forms of treatment for acute hematogenous osteomyelitis: first the systemic or antibiotic treatment and second, early surgical intervention with evacuation of the osteomyelitic abscess. Both treatments are good and have equal support from their advocates.

The present study was undertaken to determine the relative merits of emergency versus delayed surgical treatment and combined chemotherapy—antibiotic treatment. Based upon the roentgenographic evidence, local and constitutional manifestations, and blood cultures, 130 cases lend themselves suitable for this study. Seventy-eight of 130 patients were treated by emergency surgery, 31 by delayed surgery and 30 by chemotherapy.

For each of the above categories the authors sought a comparison relative to (1) mortality, (2) duration of disease, (3) recurrence, and (4) metastatic bone lesions. The mortality rate was as follows: emergency surgery 9 per cent, delayed surgery 3 per cent, chemotherapy none. Duration of the disease disclosed an average of 714 days for the emergency surgery, 360 days for the delayed surgically treated cases, and 169 days for the chemotherapy group. Recurrence, in the same order was 40 per cent, 22 per cent, and 10 per cent, respectively. Metastatic bone lesions occurred in 13, 22 and 10 per cent, respectively.

From the current investigation, the authors made the following observations:

1. The best results were obtained in patients treated via systemic approaches.

2. Delayed surgical treatment was not fraught with danger or increased morbidity.

3. The distribution of mortality was none among the systemically treated patients, 1 in the delayed surgery group and 7 in the emergency surgery group.

4. Early diagnosis and early antibiotic treatment should be established.

5. Surgical treatment of bone abscesses should be delayed and deferred when possible. Small osteomyelitic abscesses have the ability to absorb without surgical measures.

6. Chemotherapy and antibiotic therapy should be extended 2 weeks after the cessation of septic manifestations. Too early a withdrawal of these drugs has, in the hands of the authors, resulted in acute exacerbations of the disease.

Discussions by Phemister, Dickson, Seldon, Farmer, Altmeier and Nachlas follow the article.

SAMUEL L. GOVERNAUX, M.D.

The Surgical Treatment of Intractable Plantar Warts. JAMES A. DICKSON. *J Bone Surg.* 1948, 30-A, 757.

Whereas 90 per cent of the plantar warts respond to a conservative regimen, the remaining 10 per cent require radical treatment. Verruca plantaris varies in depth, size and location. It may extend to the plantar fascia, tendon sheaths (with ulceration) and to the metatarsal heads, producing intractable pressure pain.

Undoubtedly some plantar ulcerations are produced by escharotics, x-rays, and electrocoagulative treatments. Such large ulcerating areas, obviously are not amenable to simple excision. Radical treatment, such as excision of the involved metatarsal head with its corresponding toe should be the treatment of choice.

In residual large plantar skin defects, the author recommends whole-thickness skin grafting, in addition to wedge-shaped excision of the skin and partial or total metatarsectomy.

Sesamoidectomy with removal of the warty area may be indicated in cases in which these bones are out of line and are producing the ulcerations.

Twenty-five patients have been operated upon by the author. This treatment is recommended only in resistant cases.

SAMUEL L. GOVERNAUX, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Segmental Arterial Spasm Associated with Supracondylar Fracture of the Elbow: Report of a Case. A. DALE COCKSILL. *Surg. Clin. A. America* 1948 28 467

Segmental arterial spasm described in the literature as arterial spasm, traumatic segmentary inhibition of the arteries, arterial contusion, etc., is a relatively rare but serious condition in civilian practice. The physician must be alert to the diagnosis lest a salvageable limb be lost.

The case is reported of a supracondylar fracture of the elbow in an 8-year-old boy who 4 hours after closed reduction and Kirschner wire traction maintained cold, discolored fingers. Eighteen hours later in spite of repeated attempts to manipulate the fragment thought to be impinging on the brachial artery the appearance had not changed. Operative exposure revealed a contused artery in marked spasm which did not lessen when the fragments were easily and exactly realigned. Dramatic improvement, however, was observed within 30 minutes following a 2 per cent procaine paravertebral sympathetic block. Twenty months after treatment the patient had an excellent anatomic and functional result.

Paravertebral sympathetic block should be employed early in the condition for its diagnostic and therapeutic actions for regardless of the disputed etiology of the condition, sympathetic paralysis constitutes the most rational means of attack. Periaxillary sympathectomy and resection of the involved segment of vessel are ineffective, sometimes difficult, and of limited value. Operative intervention may often make a bad situation worse. Such a case in which open reduction was accomplished in the presence of marked vasospasm, is cited to illustrate that a limb may be lost under such circumstances.

ALLAN D. CALLOW, M.D.

"Functional" Subclavian Arterial Murmurs: Possible Relation to Scalenus Anticus Syndrome, Costoclavicular Compression, or the Neurovascular Syndrome of Wright. JAMES D. MERRITT and R. BERNARD POMERANTZ. *Ann. Surg.* 1948 127 655-658

During the course of routine examination of 619 applicants for positions 21 patients came to attention because of a systolic murmur over the subclavian artery. The patients were predominantly young females who presented no abnormal findings on physical examination and had no symptoms.

The murmur occurred with greater frequency on the left side than on the right and was occasionally present on both sides. The murmur was loud and constant when the examination was performed while the patient's hands were held on the hips, was less frequently heard in the relaxed sitting position, and

was absent in the recumbent position. Abduction of the arms increased the intensity of the murmur up to abduction from 135 to 150 degrees when the murmur disappeared altogether because the blood flow to the arm as ascertained from the radial pulse and blood pressure had been obliterated.

When the murmur occurred on one side only it was noted that abduction of the arms caused a greater fall in the blood pressure in the arm on the side of the murmur than in the other arm.

The author believes that one case was due to costo-clavicular compression and the others probably represented the neurovascular syndrome of Wright.

THEODORE B. MASSELL, M.D.

Portacaval Shunts in the Treatment of Portal Hypertension. ROBERT R. LINTON. *J. England* 1948 238 723

In the treatment of portal hypertension the most satisfactory portacaval shunt seems to be an end-to-side suture type of splenorenal anastomosis performed at the same operation at which the spleen is removed. Four cases of Banti's syndrome are presented in which various other types of procedures had previously been attempted without success. Three of the patients had splenectomies so that the splenic vein was no longer available for anastomosis.

Other types of portacaval shunt were performed such as anastomosis of the superior mesenteric vein to the inferior vena cava in one case and of the inferior mesenteric vein to the left ovarian vein in another case. Twenty-two and 14 months respectively have passed since the shunts were performed without evidence of esophagogastrintestinal hemorrhages.

The patient who was not splenectomized had been subjected to an extensive intraperitoneal omentopexy and ligation of the splenic artery. Despite the dense adhesions resulting from these procedures a successful splenorenal shunt was performed.

A direct portacaval anastomosis was not possible in 3 of these cases because of a cavernomatous transformation of the portal veins.

It is suggested that splenectomy should not be done for portal hypertension unless one is prepared to do a splenorenal anastomosis at the same operation since this may be the only opportunity to construct a satisfactory shunt.

THEODORE B. MASSELL, M.D.

Aneurysm of the Left Common Iliac Artery Secondary to a Traumatic Arteriovenous Fistula of the Left Popliteal Vessels. J. M. DONALD. *Ann. Surg.* 1948 127 6.

The author introduces this case report because of the infrequency of accounts of an aneurysm developing proximal to an arteriovenous fistula. This patient suffered a bullet wound of the left popliteal

region 43 years previously and developed a pulsating mass in the popliteal region with swelling of the extremity. Varicose veins developed and a subsequent ulcer which healed with difficulty. Pigmentary changes in the skin also occurred. More recently evidences of myocardial insufficiency were noted. In the past year a pulsating mass appeared in the left lower abdominal quadrant and became progressively larger. Examination revealed findings of an arteriovenous fistula in the left popliteal region, aneurysm of the left common iliac artery and cardiac enlargement with myocardial damage. The arteriovenous communication was excised by a double ligation proximal to the fistula and a quadruple ligation (anterior and posterior tibial vessels) distally. Eighteen months postoperatively the iliac aneurysm had decreased to one third of its original size and there was clinical evidence of myocardial disease.

In his discussion the author points out that proximal arterial dilatation occurs in the majority of long-standing cases; this enlargement with the increase in blood flow is an effort to compensate for the relative ischemia existing distal to the fistula. The enlargement of the artery is directly proportional to (1) the size of the fistula, (2) the volume of blood short-circuited into the venous system at the fistula, and (3) the duration of the fistula.

Degenerative changes in the artery proximal to an arteriovenous fistula occur commonly and aneurysmal dilatations are thus a potential complication in all long-standing cases. The degree of improvement of such an aneurysm after elimination of the fistula will depend on the amount of damage which has already taken place in the artery and which may be irreversible. EDWARD H. CAMP, M.D.

Aneurysm following Surgical Procedures. DANIEL C. ELIOT, *J. N. S.* 3:272, 1943, 7 figs.

The purpose of this article was to demonstrate the possibility of arterial injury in the course of operation eventuating in an aneurysm or arteriovenous fistula. From a review of the literature on this subject it seems evident that an arteriovenous communication may be produced in any operation but it is most likely that the lesion is produced when vessels are transected and ligated, an artery and vein being injured simultaneously by the needle and an opening made through which the communication is established. Care should be taken that no more than a single vessel be included in a transfusion suture.

In a personal series of approximately 650 operations for aneurysm and arteriovenous fistula, the author noted that 6 or approximately 1 per cent, of the cases followed some operative trauma. Five of

these cases are reported in detail: 3 being false aneurysms of the brachial artery, one following venipuncture and the other following incision and drainage of an abscess; 1 was a false aneurysm of the external iliac artery following hemiorrhaphy; 1 was an arteriovenous fistula of the facial vessels following procaine injection for dental extraction; and 1 was an arteriovenous aneurysm of the renal pedicle following nephrectomy. EDWARD H. CAMP, M.D.

Local Heparin Treatment of Thrombosis following Arterial Resection. PERITTI HOSKANYI, *A. M. J. Surg.* 64:337, 1942.

Although heparin is generally considered to have no direct or indirect thrombolytic action, clinical experience (e.g. in thrombosis of the retinal vessels) has shown that small fairly fresh clots may dissolve under heparin treatment. This fact was further confirmed by experimental studies of mechanically induced thromboses of the jugular vein in rabbits.

The author reports a case in which there was simultaneous perforation of the ileum and rupture of the left common femoral artery as the result of external trauma. The intestine was repaired and an attempt was made to reconstruct the injured artery but a new thrombus immediately formed at the line of arterial suture.

Two and one-half cubic centimeters of heparin solution were injected directly into the thrombus, 0.5 c.c. was introduced into the external iliac artery and 2.5 c.c. were given intravenously after the completion of the operation. No subsequent injections of heparin were given because of persistent hemorrhage from the operative wound. After 24 hours the heparin effect had to be inactivated by a protamine sulfate injection and blood transfusion.

For the first 3 days after operation there was no pulsation in the femoral artery but on the morning of the third postoperative day strong pulsation was palpated in the femoral artery peripheral to the injury as far as the two arteries of the dorsum of the foot. The occlusion had thus dissolved before 48 hours had elapsed after heparinization.

The thrombolysis is attributed chiefly to the endothermic heparin since the freely circulating heparin was inactivated prior to the resolution of the thrombus. The author suggests that the lysis of large clots requires close contact of the heparin in high concentration with the thrombus. General heparinization fails to bring a sufficient concentration of the drug into contact with most of the clot but intrathrombotic injection seems to overcome that difficulty.

THEODORE B. MARSHALL, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Cardiac Resuscitation ROBERT D. DRIPPS, CHARLES K. KIRBY, JULIAN JOHNSON and WILLIAM H. EBB
Ann. Surg. 1948 127 592

Sudden cessation of cardiac activity is an emergency the recognition and treatment of which are poorly understood by many surgeons. Treatment must be boldly executed according to a carefully worked out plan consisting primarily of artificial respiration with 100 per cent oxygen and cardiac massage. The success or failure of such a program depends entirely on the length of time the brain is without blood supply. If restoration of the circulation occurs within 3 to 5 minutes, complete recovery can be expected, particularly in young, previously healthy individuals. Two problems demand attention: the heart must be restarted and the central nervous system must not be deprived of oxygenated blood for more than from 3 to 4 minutes. Cerebral anemia of greater duration is followed by widespread cerebral cortical destruction and death. The course of 4 patients on whom cardiac resuscitation was successful is described. Two of these patients suffered cerebral anemia for a period longer than 3 to 4 minutes.

When no peripheral pulse is palpable and blood pressure cannot be obtained by auscultation, three possibilities must be considered: (1) the heart has stopped beating entirely; (2) the ventricles are fibrillating; or (3) cardiac contractions are so feeble that insufficient blood is ejected to raise arterial pressure to the level at which a peripheral pulse can be felt.

The method of artificial respiration depends upon the circumstances. If cardiac arrest has occurred in the operating room, an anesthesia machine is satisfactory. Manual compression of the breathing bag will inflate the lungs and the elastic recoil of the respiratory organs completes the cycle. Although respiration (normal or artificial) can cause some blood to circulate, the most effective mechanism for movement of blood is the pumping action of a contracting heart.

A transverse incision in the fourth left intercostal space is best. The fourth and fifth ribs can readily be spread apart and the heart is grasped by the operator. Exposure may be increased by dividing the fourth and fifth costal cartilages. A direct approach through the chest wall is superior to an abdominal incision with an attempt to reach the heart through either an intact or an incised diaphragm. Opening of the pericardium is not required. The heart is compressed firmly at the rate of 20 to 40 times per minute, depending upon the adequacy with which the ventricles fill between compressions. Each compression raises the arterial pressure 60 to 70 mm. Hg, and a pulse can often be felt in a peripheral vessel. To increase blood flow through the coronary

arteries, the aorta may be occasionally compressed just above these vessels. Secretions which accumulate in the pharynx and tracheobronchial tree must be aspirated. Prophylactic injections of penicillin are often advisable to minimize pulmonary infection. The patient must be turned frequently from side to side to avoid hypostatic congestion in the dependent portions of the lungs. Urinary output must be maintained by an adequate fluid intake and constant attention must be paid to the bladder.

In general, if prompt diagnosis is followed by prompt therapy, the heart can be started again. If on the other hand there is hesitancy rather than boldness, or if intravenous therapy is attempted before attention is directed towards the heart, the myocardium may have been sufficiently damaged by anoxia to resist all efforts at resuscitation. When the heart returns to a regular rhythm and blood pressure is maintained, spontaneous respiratory activity can be expected to reappear within 5 to 30 minutes.

C. FRED GOERTZ, M.D.

Skin Grafts. The Spiral Dressing (Injertos de piel. El apósito espiral). HÉCTOR MARINO. *Rev. As. méd. argent.* 1947 61 463

The author proposes a practical way of immobilizing skin grafts laid on concave surfaces, such as the segments of a limb, especially if different areas must be grafted in one sitting. In this particular instance, a compressive dressing alone cannot be used before the end of the procedure. In addition, it might wrinkle or displace the graft if it is not applied with exacting technique.

The spiral dressing consists of a cellophane or cotton ribbon or simply a No. 16 or 40 cotton thread wound around the limb, inclosing the graft. Once the graft has been stretched on the raw surface, with or without suture of the borders, the ribbon is applied with utmost care and very slight traction by the surgeon himself. The turns are made at a distance of more or less than 5 mm. from each other and the graft thus remains attached to the surface under gentle pressure. Any excess of traction might bring circulatory troubles.

The ends can be knotted in a last circular turn or still better attached to the skin by a final stitch. The latter method avoids circular turns which easily produce impairment of the surface circulation.

Covering the limb with a coat of adhesive (mastic) before winding the cotton tape around it helps to keep the turns in place.

It is important to remember that if an Esmarch bandage or the hemostatic cuff has been employed, the restoration of the circulation is imperative before the spiral dressing is applied.

According to the author, the spiral dressing has the following advantages over the plain or grease dressing.

1. It presents a quick and simple way of immobilizing grafts, allowing simultaneous operations on different sites of a limb.

2. As the graft remains perfectly attached the number of sutures can be greatly reduced.

3. The graft can be observed until the operation is finished and the final dressing is applied.

4. The outer dressing can be removed without danger of pulling off the graft which is caged under the ribbon turns.

5. Sutures can be removed and any sort of subcutaneous collections drained without disturbing the immobilization of the graft.

The use of the spiral dressing does not prevent correct postoperative immobilization with a compression bandage and, if necessary, a plaster cast. The author advocates the covering of the grafted area with sterile gauze, held in place with an elastic bandage and enclosure with a plaster cast. The elastic bandage is covered with a layer of crepe paper to facilitate the later removal of the cast.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

The Preparation of Granulating Wounds for Grafting (a Method) JAMES T. MILLIE, JOHN B. PATTERSON, and R. EUGENE HOSKE. *Plast. Reconstr. Surg.* 1918 3 445

A large majority of the patients with burns who come to the surgeon are the ones who have survived the acute phase and have been referred because of full thickness skin loss of varying extent. Most of the wounds are grossly infected and covered with exuberant granulations.

When a case of this type is admitted to the hospital the usually malodorous ointment dressing is removed with aseptic technique, a wound culture and photograph are taken and laboratory work in the form of Kahn blood plasma protein and albumin and globulin tests, a complete blood count, uric analysis and blood typing is ordered. All crusts and necrotic tissue are then removed, the surrounding skin is washed and shaved, following which a single layer of nonoverlapping 4 by 4 mesh plain sterile gauze is applied over the granulating surface. This is followed by wet saline dressings. Evaporation and capillary contamination are minimized by wrapping the part in sterile cellophane or similar moisture-proof material. The saline dressings are then changed every 4 hours down to the fine mesh gauze by the nursing staff with sterile technique. The fine mesh gauze is usually left undisturbed for a week unless necrotic tissue is present, in which event it is changed every 5 days until all separating tissue has been removed.

During the interval the patient's temperature usually returns to normal, his appetite improves, and the blood picture is brought back to near normal by blood transfusions. By the third hospital day the admission wound culture report is available and if this reveals pathogenic gram positive cocci, penicillin

in the amount of from 5,000 to 15,000 units may be added to each ounce of saline solution used. If pathogenic gram negative bacilli are reported, from 0.1 to full strength soluble furacin solution may be used to advantage. However neither is recommended for routine use since adequate drainage of the granulating wound will usually permit the tissues themselves to either destroy or effectively reduce the bacterial flora.

On the seventh hospital day the patient is taken to surgery where under general anesthesia, the fine mesh gauze is removed, a check culture is taken, all exuberant granulations are cut down to a firm base, fresh sterile fine mesh gauze is applied in a single layer and the wet saline dressings every 4 hours are resumed. The check culture is usually either negative or the number of bacteria is appreciably reduced.

By the tenth hospital day the granulating bed is usually clean in appearance and ready for skin grafting. Under general anesthesia the recently applied fine mesh gauze is removed, the part covered with hot saline packs, and the grafts taken with a Padgett dermatome. These are then placed upon the granulating bed and fixed in position with sutures and a pressure dressing over fine mesh vaseline gauze. An attempt is made to cover the entire area in one operation if the wound is considered not too extensive, the skin is available, and the condition of the patient permits.

If however the area is too extensive such as two entire lower extremities, one will be grafted and the other kept clean for covering at an early date. The intramuscular administration of penicillin in the amount of 50,000 units every 3 hours is started the day before surgery and continued until the first postoperative dressing on the third postoperative day. At the time of this dressing all sutures are removed, any blebs, pustules, or hematomas are incised or excised and any necrotic graft or over-lapping graft edges are excised. Fine mesh gauze is again applied in a single layer and wet saline pressure dressings are instituted. These are changed down to the fine mesh gauze every 12 hours and continued for from 4 to 7 days as the case may warrant. All dressings can be discontinued by the tenth postoperative day if the take is in the upper extremities. Any remaining granulating areas may then be strapped with adhesive tape until epithelization is complete. If the area grafted is a lower extremity an elastic bandage must be worn until the graft has adjusted itself to dependent circulation.

The cause of any appreciable loss of the graft will usually be found to be due to infection, hematoma, improper pressure immobilization or both of the latter in that order.

The advantages of the fine mesh gauze treatment of granulating wounds are as follows:

1. A single nonoverlapping layer of fine mesh gauze allows the drainage of exudate through it into the overlying wet dressings, which in turn can be changed frequently and relatively painlessly.

2. Removal of the granulations prior to the day of skin grafting results in a cleaner wound and a more receptive bed and minimizes bleeding beneath the graft.

3. Changing the fine mesh gauze 2 or 3 days prior to grafting likewise minimizes the oozing from the granulating wound when the gauze is removed on the day that the grafts are placed.

4. Following the skin grafting the fine mesh gauze allows the spread of epithelium with a minimum of disturbance.

5. All dressings other than the initial one those in which the fine mesh gauze is changed and the initial dressing after skin grafting can be done by trained hospital personnel.

FRANK F. KANTHAK, M.D.

ANESTHESIA

Animal Experiments with Procaine and Related Drugs. FREDERICK M. ALLEN and FRANK K. SARFORD, *Current Res. Anesth.*, 1948, 27, 131.

These experiments deal with the clinical effects of the procaine class of drugs on animals chiefly rats. They concern mainly the systemic effects of injections into the tissues and thus are somewhat intermediate between the clinical methods of local infiltration and intravenous anesthesia.

The approximate toxic or lethal dosage of procaine in rats was ascertained in intravenous intraperitoneal, intramuscular and subcutaneous injections. Experiments were done to study the prevention of toxic or lethal effects by artificial slowing of the absorption. Epinephrine and local temperature reduction delayed absorption. The possible usefulness of colloid or lipid emulsions is undetermined. The availability of the tourniquet adds to the safety of large procaine injections in the limbs. The higher the poisonous dose the greater must be the number of alternate applications and releases of the constriction.

The effects of procaine overdosage in animals are dyspnea, convulsions and collapse and the reaction to painful stimuli are exaggerated. Therefore procaine alone is entirely unsuitable for systemic anesthesia in the common laboratory animals. It can reduce the dose and increase the efficiency of a barbiturate used for anesthesia, but the barbiturate must predominate and the procaine merely be a supplement. Analogues of procaine (intracaine, metacaine, pontocaine, nupercaine) were studied. They behaved similarly to procaine but were more toxic.

Sodium pentothal in 0.1 per cent concentration can be mixed with procaine without precipitation. The analogues of procaine are precipitated by pentothal in still weaker concentrations.

Pentothal sodium inhibited procaine convulsions in rats but did not counteract the lethal effects nor was procaine an antidote to lethal doses of pentothal. Some protection seems to be offered by nupercaine.

Local tissue necrosis complicates the effects of procaine injections in rats. Procaine appears to neither mitigate nor aggravate secondary shock. There is

evidence of great difference in the effects of procaine in animals and man. MARY KARP, M.D.

Regulation of Blood Pressure during Spinal Anesthesia: Observations on Intramuscular Pressure and Skin Temperature. H. MIKLOSZY and A. DE VRIES, *Anesthesiology* 1948, 9, 253.

Among the theories advanced to explain the hypotension of spinal anesthesia, only two are supported by present-day investigators i.e. the theory of stagnation in the postarteriolar bed and the theory of arteriolar dilatation. This investigation has been carried out to acquire further information on the mechanism of blood pressure regulation during spinal anesthesia in the light of these theories.

Intramuscular pressure in the lower and upper extremities of 11 patients under spinal anesthesia was measured to investigate the possible correlation between skeletal muscle tone and blood pressure fall during spinal anesthesia. No significant decrease of intramuscular pressure developed in the paralyzed lower extremities. Thus it was felt that a decreased skeletal muscle tone cannot be the main cause of blood pressure fall in spinal anesthesia.

Skin temperature measurements were performed in the lower and upper extremities of 21 patients under spinal anesthesia to ascertain the role of vasodilation in producing hypotension and of compensatory vasoconstriction in preventing it during spinal anesthesia. The findings show a definite correlation between the degree of blood pressure drop and the upper level reached by the spinal anesthesia. The question why compensatory vasoconstriction occurs in some cases and not in others can now be answered.

Arteriolar dilatation resulting from vasoconstrictor paralysis in the anesthetized part of the body is the principal cause of blood pressure fall during spinal anesthesia. Compensatory vasoconstriction occurs in the area not under the effect of the anesthetic agent. The ratio between the area of vasodilation and that of compensatory vasoconstriction determines the degree of blood pressure drop in spinal anesthesia. In high spinal anesthesia the majority of vasoconstrictor fibers including those supplying the upper extremities (fourth to eighth thoracic) are blocked and hypotension ensues. In low spinal anesthesia a sufficient number of vasoconstrictor fibers are left intact to prevent a major drop in blood pressure. MARY FRANCES FOX, M.D.

SURGICAL INSTRUMENTS AND APPARATUS

Auriculomastoid Tube Pedicle for Otoplasty. DAN N. STEINMANN, *Plast. Reconstr. Surg.* 1948, 3, 351.

Restoration of auricular deformities taxes the ingenuity of the plastic surgeon. The complex topography of the auricle calls for the solution of three problems: whether the reconstruction is to be partial or total. First support must be supplied by autogenous or homogenous cartilage with duplication of near normal configuration. Second soft tissue covering must be obtained either from adjacent or distant

tissues. Third immobilization of the reconstructed auricle to the side of the head at the correct angle must be attained. The pitfalls in solving these difficulties are discussed.

The report of a problem in partial reconstruction of the auricle in a patient with marked hypertrichiasis is presented. As the hypertrichiasis precluded the use of the usual donor sites for soft tissue coverage, resort was made to the skin of the medial surface of the remaining auricle and the skin over the mastoid area was used to form a tubed pedicle flap later to become the helix. Cartilage for support was implanted under a postauricular flap. Following this the posterior surface of the postauricular flap was skin grafted to form normal auriculopetal angle. The tubed pedicle flap was then utilized to form the helix.

Excellent photographs and diagrammatic sketches clearly indicate the various operative steps (eight) which were completed in 3 months.

EARL H. KLABOWITZ M.D.

Observations on an Absorbable Powder to Replace Talc. E. L. MACQUINDY and J. P. TOLLMAN. *Surg 948, 3 786*

The use of talc as a lubricant on gloves in surgery has been questioned for the past 10 years. Several thorns have called attention to the dangers of talc as a factor in the production of adhesions and of talc granulomas. Difficulty has been encountered in finding an acceptable substitute for talc.

Talc or soapstone was found in the incinerated lung of a woman supposedly dying from tuberculosis, who had worked for some years in the handling of products made from soapstone.

Since 99 there have appeared various articles describing a condition found particularly in the peritoneum resembling tuberculosis but which was recognized as not being a true tuberculous lesion. It was described as pseudotuberculosis.

Work has been done on absorbable starch powder. It consists of a mixture of amylose and amylopectins derived from cornstarch which has been treated by physical and chemical means to improve its lubricating value and to prevent gelatinization when autoclaved.

The first portion of investigation was an allergenic study to determine whether human beings could have

become previously sensitized to this or similar starches. It was also attempted by means of parenteral injections to sensitize animals.

The second section of the study consisted of injecting starch powder intraperitoneally and subcutaneously in rabbits and guinea pigs, and intraperitoneally alone in dogs to observe its effect. These particular experiments were also contrasted with similar experiments on animals using talc. The talc experiments were carried out to confirm previously reported work on the use of this powder.

The third portion of the study consisted of inhalation experiments in which rabbits were exposed to atmospheres of talc and of starch powder under the same conditions.

Studies were made to determine existence of a previously acquired sensitivity; this starch. Patch tests were made on 50 adult males. The tests were applied and left in place for 72 hours with readings recorded at the end of 24, 48, and 72 hours. No positive reactions were obtained.

An extract was made of this starch in the manner used to prepare allergens for use in the allergy department. Eighty-one patients with allergenic backgrounds in the allergy clinic at the University of Nebraska were tested both by scratch and by intracutaneous tests. No reactions were found in this group. In so far as the results were concerned no previous sensitivity to this starch could be found.

No sensitivity to this starch was found in the group of human beings tested.

There was nothing to prove that the animals became sensitive when injected parenterally with this absorbable powder.

No peritoneal adhesions occurred in any of the animals in which starch powder was used.

The work showed that a chemically modified starch powder when placed in the tissue of animals, is nonirritating and is readily absorbed from the peritoneal cavity.

The work confirms that of previous authors that talc is irritating when placed in the peritoneal cavity of dogs and rabbits, and in the lungs of rabbits.

The evidence indicates that starch powder is a safe replacement for talc for surgical and other purposes for which this commodity is widely used.

HARRY W. FINE, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Cerebral Angiography JOHN R. GREEN and ROMAN ARANA. *Am J Roentg* 1948 59 617

The authors give a brief summary of the history of cerebral angiography and state that in America the method is used rarely for the diagnosis of cerebral neoplasms.

Angiographic anatomy Two pairs of arterial trunks bring blood to the brain. The two carotid arteries and their branches supply the frontal parietal and lateral portion of the temporal lobes the anterior half of the thalamus and the corpus striatum. The two vertebral arteries and their branches supply the caudal region of the brain including the inferior portions of the temporal lobes occipital lobes posterior part of the thalamus brain stem and cerebellum. The distribution of the entire arterial system of the brain is described in great detail. Normal arteriograms obtained by the carotid and vertebral injections as well as diagrams are used for illustration.

The venous system of the brain is also considered. The venous channels are divided and considered as superficial cerebral veins deep cerebral veins and dural sinuses.

Circulation time It takes approximately 4 seconds for the blood to pass from the carotid artery into the dural sinuses. The arterial phase lasts one second and the capillary phase is usually complete within 4 to 5 seconds after the injection of the opaque medium. By proper timing it is possible to visualize any of the phases roentgenographically. When the external carotid is visualized simultaneously and in injection of the vertebral system the rate of flow is a few seconds slower. Likewise increased intracranial pressure certain neoplasms, aneurysms and vascular occlusions often slow down the circulation time.

Techniques Cerebral angiography can be done by direct injection of the internal carotid or vertebral arteries, or by injection of their tributaries namely, the common carotid and subclavian arteries respectively.

During the past 5 years angiographic studies were made at the Illinois Neuropsychiatric Institute by over 10 different operators and teams. The percutaneous method of injection was preferred this giving satisfactory information in 71 per cent of the cases. The authors believe that with experience a good operating team should attain close to a 100 per cent result. The cases in which the percutaneous method fails are subjected to surgical exposure of the artery. Sodium pentothal anesthesia by intravenous drip is used. Routine endotracheal intubation serves as a precaution against the possibility of laryngeal spasm during manipulation of the neck although it is not essential.

TABLE I—CLINICAL ANALYSIS OF 107 ANGIOGRAPHIC EXAMINATIONS

	No. cases
1. Diseases of Blood Vessels	
a. Saccular arterial aneurysms	11
b. Malformations and tumors	
1. Arterial angiomas	2
2. Venous angioma (Sturge-Weber)	1
3. Linder's disease	1
c. Occlusions	
1. Traumatic	1
2. Embolic	1
3. Eclampsic	1
Total	19
2. Neoplasms	
a. Meningiomas	7
b. Sarcoma of meninges	2
c. Gliomas	
1. Astrocytomas	4
2. Glioblastoma multiforme	28
3. Miscellaneous	
Subependymal plate	1
Third ventricle	1
d. Cancer metastases	7
e. Unverified tumors of the brain	8
Total	58
3. Miscellaneous Conditions	
a. Subdural hematoma	1
b. Brain abscess	1
c. Others	3
Total	5
4. Normal Angiograms	26

The authors give a detailed description of the injection technique as well as of the roentgenologic technique.

Contrast substances The most commonly used opaque media for cerebral angiography are (1) thorotrast, (2) diodrast, (3) parabrodil and (4) ethyl triiodine stearate. The relative merits of each is discussed. Only the first two substances are being used in American clinics. The authors prefer diodrast since, in contradistinction to thorotrast it is completely excreted and has no potential danger from radioactivity. Allergic reactions may occur with it but a preliminary sublingual test applied routinely would put one on guard. The injection of the diodrast is painful and therefore a general anesthesia is required.

Material The authors publish their observations on 107 cases of cerebral angiography. There was not a single mortality and a transient allergic reaction was noted in only 6 instances. The distribution of the cases is shown in Table I.

Diseases of blood vessels Cerebral angiography offers a most specific method of diagnosis in this group of entities. In the authors series saccular aneurysms comprised the majority of the vascular

anomalies. They usually were (1) congenital (2) arteriosclerotic, and (3) mycotic in origin. In most cases, it was possible to visualize the exact site, size, and anatomic relationship of the aneurysms. This knowledge is of invaluable aid to the operator in planning whether to merely ligate the internal carotid artery in the neck or to resort to an intracranial intervention. It must be pointed out that in some instances although the clinical diagnosis of aneurysm seemed to be certain, the angiogram remained negative. This can happen when the neck of the aneurysm is too small to receive the contrast substance or if the aneurysm is filled with hematoma. In such cases the neurosurgeon must proceed without the aid of angiography.

Neoplasms. The most important angiographic alterations in neoplasms are (1) displacement of normal vessels, (2) pathological changes within the blood vessels of certain tumors, and (3) dilatation of vessels supplying a tumor, i.e., meningiomas. Therefore angiography offers, in addition to the exact localization of the neoplasm, the possibility of a histopathologic evaluation of the type of tumor.

The authors series includes 58 cases with neoplasms. In the majority there was evidence of increased intracranial pressure at the time of examination. Angiography did not lead to aggravation of the symptoms or signs in a single case, so that the method is less dangerous than ventriculography.

The angiographic pattern is discussed in detail for (1) meningiomas (2) gliomas, comprising the two important subgroups of (a) glioblastoma multiforme and (b) astrocytoma and (3) cancer metastases. The glioblastoma multiforme was diagnosed in 22 out of 25 verified cases and the cancer metastases in 3 out of 7 verified cases.

Indications and contraindications. Angiography is contraindicated in acute cerebrovascular hemorrhages, thromboses, or emboli and is hazardous in old patients with cardiac decompensation, hypertension, and advanced atherosclerosis. In suspected brain abscess and chronic subdural hematomas it should be used only after other diagnostic methods have failed.

Air studies are preferred for the localization of obscure lesions of the ventricular system, of the posterior fossa, and those above the tentorium in which lateralizing signs are absent. On the other hand, angiography is the method of choice in aneurysms, vascular malformations, parasellar lesions, and in supratentorial pathology if lateralizing findings are present.

The authors give the case histories of 15 patients and use the respective roentgenograms for illustration. A bibliography of 60 articles is appended.

T. LEUCOTIA, M.D.

Plain Radiography of the Skull in the Diagnosis of Intracranial Tumors. DAVID STEINHOUSE. *Brit. J. Radiol.*, 1948, 21, 287.

The author presents an analysis of the pertinent radiological findings in plain films of the skull in 200

verified cases of intracranial tumor at the Kilmara Hospital, Stirlingshire, Scotland. In 22 per cent of the cases radiographic signs of increased intracranial tension were indicated by diastasis of sutures, increased convolutional markings or thinning or erosion of the domum sellae. Increased convolutional markings were accepted as of significance but only with caution; the group included only 4 cases—3 children who also showed diastasis of sutures, and 1 adult with a cerebellar astrocytoma in whom the calvarium had a distinct beaten silver appearance. Localizing signs were found in 30 per cent of the patients in the form of shift of the calcified pineal, abnormal intracranial calcification, bone erosion, new bone formation, and occasional spectacular widening of vascular channels so pronounced as to fall outside the limit of normal variation. While each sign was indicative of lesion, it was of course recognized that they were not in themselves pathognomonic of tumor.

Sellar changes were found of value in localization only if in the form of uniform expansion of the sella. The most frequent sellar changes were thinning or erosion of the domum, but these were common both to tumors in or near the sella and to those at a distance from it (metasellar lesions). The degree of sellar destruction and the degree of hydrocephalus were found roughly proportional to each other in metasellar lesions, but there was no satisfactory evidence that the hydrocephalus itself was the cause of the bone destruction. The possibility is offered that at least a contributory cause of such sellar changes may be the finding, in some cases, of dilated anterior end of the third ventricle in contact with the sella.

Abnormal intracranial calcifications (and ossifications) were, of course, of definite help in localization and occurred in 7 per cent of the cases, composing a group of meningiomas, astrocytomas, suprasellar cysts and godendroglioma, a dermoid and a hemangioma, and including 4 osteomas. The attachment of the latter to the base of the skull and their homogenous and very marked density with lobulated periphery made them recognizable radiographically as osteomas, and the dermoid could also be diagnosed from the roentgenogram because a tooth was visualized. Otherwise the author found the position and pattern of solitary intracranial calcification not dependable as an indication of the pathological nature of the lesion—not even as to whether it was a tumor. All 3 instances of suprasellar calcification in this group occurred in cranioopharyngiomas, but on reviewing the literature the author found that Dale in 1934 had reported suprasellar calcification in a chiasmatic glioma and in a suprasellar meningioma.

Shift of the calcified pineal laterally or in the sagittal plane may be a valuable sign in localization. In this series 33 calcified pineals were visible in anteroposterior projection and of these 13 showed a lateral shift. In each case the tumor was found to lie in the hemisphere opposite to the direction of shift. No shift is to be expected in cases of tumor situated in the posterior fossa, in very small cerebral tumors in

multiple tumors evenly divided in mass between the cerebral hemispheres or in small supratentorial mid line tumors. Shift of the calcified pineal in the sagittal plane was shown in 15 cases. All were supratentorial, and in each the shift was away from the tumor. Of these in 5 cases a lateral shift was also shown so that not only could it be told which hemisphere was involved but roughly which half of it.

Extracerebral tumors have a common capacity subject to radiographic record that of bone erosion. Among such tumors in this study were those of the pituitary, a chordoma, some acoustic neuromas and several meningiomas especially those of the base. New bone formation on the other hand was stimulated only by 2 meningiomas located near the midline of the vault and although rather characteristic in appearance was known to have been imitated by lesions of other origin such as osteoplastic metastases, primary sarcoma, hemangioma and os teitis fibrosa.

LILLIAN DONALDSON M.D.

Radiology in Heart Surgery T. HOLMES SELLORS.
Brit J Radiol., 1948 21: 226.

The author, a thoracic surgeon, emphasizes the importance of accurate diagnosis in the advancement of cardiac surgery and the need for teamwork between the physician, the radiologist and the surgeon. He believes that comprehensive roentgen examination not only in the standard positions should be carried out but that careful fluoroscopy, kymography and angiocardiography are important.

Two main groups of heart disease of primary interest to the surgeon are discussed: (1) certain forms of congenital disease such as patent ductus arteriosus, coarctation of the aorta, anomalies of the aortic arch and great vessels, and Fallot's tetralogy; and (2) cardiac compression causing pericardial abnormalities, pericardial effusions, polyserositis, and constrictive pericarditis.

The author presents briefly the surgical possibilities and the differential diagnostic criteria in these conditions with emphasis on the roentgenological aspects.

The article is accompanied by good reproductions of representative diagnostic films with several kymographs.

ALLAN K. BRIDCKY M.D.

A Simplified Method of Roentgen Pelvicephalometry AUGUS K. WILSON *Am. J. Roentg.* 1948 59: 688.

Accurate roentgen measurements of the fetal skull is difficult. For the past 4 years the author has employed a method which permits accurate cephalometry in both vertex and breech presentations. The author reports his experience with the use of this method.

Since, in the majority of cases the fetal skull lies in the maternal midline and in a reasonably sagittal or lateral plane it is possible to determine the height of the skull above the film and to make corrections for distortion due to magnification thus actually calculating the desired skull dimensions. An antero-

posterior and a lateral view (at right angles to each other) is used with the patient recumbent. Knowing the target film distance and the distance from the midline of the patient to the film the height of the fetal skull above the anteroposterior view and one or more of its diameters as well as the heights of the maternal pelvic planes can be calculated.

In the case of vertex presentation four films are made. If there is a breech presentation one or two more films centered on the fetal skull are added. The films are (1) a film in a semi-erect view with the patient sitting at an angle of 45 to 55 degrees and the tube centered opposite the anterior superior iliac spine to show the pelvic shape; (2) a standard anteroposterior film to which in case of breech presentation a second 10 by 12 inch film is added centered over the skull at the higher level; (3) a lateral film made immediately after the former so as not to disturb the relative positions with the patient moved to the side of the table directly against the cassette and the tube turned horizontally supplemented by a second film if there is a breech presentation; and (4) another lateral film made with the patient erect in a true lateral view so that the femoral heads are superimposed the tube being centered as in film 3, midway between the symphysis pubis and the anterior superior spine of the ilium.

The distance from the target to the film is 40 inches. Film 3 serves to determine the heights of the fetal skull and pelvic planes. When making this film the technician also measures the distance from the midline of the patient to the surface of the wafer grid adding 1 cm. which is the distance from the surface of the grid to the film within the cassette. When film 4 is made the distance from the patient's midline to the table top is measured and to it 4.0 cm. are added, corresponding to the distance from the surface of the table to the film within the cassette in the Bucky tray.

The positioning of the patient for all four films is illustrated and the resulting roentgenograms are reproduced.

The calculations are based on the following mathematical formula:

$$\frac{\text{Tube to film distance}}{(\text{Tube to film distance}) - (\text{Object to film distance})} = \frac{\text{roentgen image diameter}}{\text{original diameter}}$$

For convenience the author constructed a false centimeter scale based on the 40 inch target film distance which is similar to that developed by Walton based on a 30 inch distance. The scale is reproduced and its use explained. As has been stated film 1 serves only to ascertain the pelvic shape. The measurements are made, in respective order on films 3, 2 and 4. The calculations and necessary corrections are described in detail.

The method has the advantage of technical simplicity with ease of calculation and evaluation of the results. The only measurements required of the technician are from the midline of the patient to

fired surfaces. The calculations can be made on wet films if need be.

This report is based on an experience gained in over 200 examinations. T. LEICHT, M.D.

On Irradiation Sickness. KAT SRELL and PIERRE ERMALA. *Ann chir gyn. fem.*, 948, 37 Supp. 1

During the past decade irradiation sickness has become a problem of considerable magnitude. It is impossible to predict who will develop radiation sickness. It may appear after the administration of 200, 600 or 1,000 roentgens. Symptoms, although variable are manifested by nausea, lassitude, anorexia, vomiting, oliguria, cramps, bloody diarrhea, low blood pressure, restlessness and prostration.

Several theories have been offered as a cause of radiation sickness: gases produced in the x-ray room, the electric field surrounding the patient, vitamin B deficiency, irradiation effects of endocrine glands, destruction of intestinal mucosa, nervous factors, histamine-like substance, and changes in the blood cholesterol contents. Of all the theories mentioned the only ones that are still supported by some authorities are the histamine-like substance and changes in blood cholesterol.

The effect of 300 roentgen irradiation on lipids showed a 60 per cent decrease in blood cholesterol and an increase of 28 per cent of the liver cholesterol. The effect was more pronounced when the dosage was raised from 300 to 1,000 roentgens.

A group of 65 adult patients was used in the present study. A determination of the chylomicron count, which is more rapid and reliable than the usual methods of chemical analysis, was made. Chylomicron is formed of lipids and is surrounded by a protective protein layer; the average size is 5×10^{-6} u and there are 80,000,000 chylomicrons per cubic centimeter of blood.

All forms of roentgen therapy were used; the dosage varying from 500 roentgens for cancer of the larynx to 350 roentgens for gynecological cancer. A 5 gm. radium pack was used to give a 732 roentgen dose to the face.

All parts of the body and different types of carcinoma were studied for the chylomicron count. Of 12 patients with head lesions treated, only 2 showed evidence of irradiation sickness; in these 2 patients the carotid sinus area was irradiated. Of 16 patients with neck lesions the carotid sinus was irradiated in 15 patients; of these 9 developed irradiation sickness. The chylomicron curves in all cases were depressed. Of 3 patients with lesions of the thorax and 2 with lesions of the extremities, none developed irradiation sickness. Of 23 patients with carcinoma of the abdomen, 5 showed evidence of irradiation sickness with typical lowering of chylomicron count. It was also noted that in some instances of prolonged irradiation the chylomicron count would tend to become lower even if the patient showed no clinical evidence of irradiation sickness. Not once was a low chylomicron count observed in a well patient.

On the basis of their studies the authors conclude that patients suffering from irradiation sickness show marked changes in the chylomicronograph. Irradiation to the lower cervical region (carotid sinus), midabdomen or pelvis produced evidence of sickness.

A daily dose exceeding 350 roentgens, if treatment were continued, would produce sickness also, an increase in the daily dose or a larger dose would show the same results. In some instances changes in the chylomicronograph were evident before the clinical symptoms.

Facts tend to support the theory that irradiation produces injurious effects which are carried from the tissue by way of the circulation. This substance is histamine-like in character. In addition, involvement of the sympathetic and parasympathetic nervous system which controls the chemical composition of the blood may be a factor.

MAURICE D. SACHS, M.D.

A New Medication for Radiation Sickness (Une nouvelle médication du mal des rayons) H. KRITZER. *Presse med.*, 948, 56, 370.

Radiation sickness with its well known symptoms, such as loss of appetite, fatigue, nausea, and vomiting, is a relatively frequent complication of roentgenotherapy occurring particularly in patients treated for pelvic or thoracic affections. Different factors have been incriminated in explaining the cause of the symptoms: the presence of ions in the treatment room, chemical changes in the organism, absorption of substances produced by the destruction of cells, particularly histamine, sympathetic or parasympathetic disequilibrium, injury of the suprarenal glands, and psychologic factors. None of these theories has given a satisfactory explanation.

Stig Kulander, after having analyzed the degree of acidity of the vomitus of 34 patients suffering from radiation sickness, found total achlorhydria in 50 and a very low degree of acidity in the 4 others. He then gave these patients a 7 per cent solution of hydrochloric acid immediately after the symptoms subsided and disappeared in the majority of cases.

The author states that he had occasion to treat 20 patients with hydrochloric acid. These patients had been treated for uterine tumor and presented a variable degree of radiation sickness. Forty-eight hours after the hydrochloric acid was given, the vomiting stopped, the nausea was attenuated, and the appetite became normal. In some cases, a state of nausea persisted but it was not serious enough to prevent the patient from eating.

The dose prescribed is as follows: 7 per cent official hydrochloric acid, from 20 to 40 drops in water before the principal meals. In certain cases with severe alimentary intolerance it is advisable to prescribe a supplementary dose of 40 drops immediately before the treatment.

In mild cases, with only nausea but no vomiting, adrenalin, vitamin P.P. and parasympathicomimetics are often sufficient for attenuating the symp-

toms. However, in severe cases with digestive intolerance and dehydration and in which discontinuation of the treatment is considered it seems that hydrochloric acid by mouth gives more effective results than any other ordinary medication used up to the present time

The Effect of Radiation on Hemopoiesis. Is There an Indirect Effect? JOHN S. LAWRENCE, WILLIAM N. VALKOTINE, and ANDREW H. DOWD. *Blood* 1948 3 593

The controversial and poorly understood problem of the presence or absence of an indirect action of roentgen rays is again investigated. This relates especially to tissues that are far removed from the site of the irradiated ones. In a review of the literature upon the subject the authors cite much evidence for and against such an effect and conclude that "it is readily apparent that the literature weighs heavily on neither side of the question."

Twenty-six successful cross circulation experiments using cats are presented. Normal animals were connected to irradiated animals in two groups: (1) shielded groups of animals whose partners were connected at the time of irradiation, and (2) those whose partners were cross circulated with a previously irradiated animal. The cross circulation required from 3 to 10 hours lasting 8 hours in the largest group. The total leucocyte and absolute lymphocyte counts were followed for 28 days.

The authors were unable to demonstrate any specific effect due to the radiation alone. They offer three possible explanations for the differences of opinion expressed by others. First, the indirect action may be due to the inclusion of larger amounts of hematopoietic tissue than those generally considered. This may be especially true in debilitated patients who have lost some of the ability to supply additional reserve cells, also the exact amount of tissue irradiated is not known in many cases. Second, a specific indirect effect may still exist even though these experiments do not support such a contention. Third, a nonspecific effect of the radiation may occur because of injury to tissue irradiated with the liberation of a circulating toxic substance. The substantial reduction in lymphoid tissue not directly injured has been well substantiated and frequently observed as a response to a variety of injurious agents. This is well shown by striking degenerative and involutionary changes in all lymphatic organs as a response to a variety of insults as described by Selye and called the alarm reaction by him. Such insults include cold, heat, surgical shock, and drugs. Radiation's indirect action may be another insult of this nature.

ROY GREENING MD

Some Hematologic Effects of Irradiation WILLIAM BLOOM and LEON O. JACOBSON. *Blood* 1948, 3 586

Two main types of study were carried out: (1) total body irradiation and (2) focal irradiation.

In the first case rabbits, mice, rats, and guinea pigs were exposed to total body irradiation with roentgen rays and gamma rays and slow and fast neutrons. The LD 50/30 days dose of each agent was used and gradually decreased until no histologic or hematologic changes were observed.

Focal irradiation was administered to a few mice through external sources using P_{22} , but largely through intravenous, intraperitoneal or intramuscular injection and inhalation of P_{22} and several other isotopes including both alpha and gamma emitters. The LD 50/30 days dose and diminishing fractions thereof were used.

In addition daily exposure with gamma and roentgen rays over periods up to 3 years was carried out.

The authors observed no evidence in the blood-forming tissues and in the peripheral blood of a primary stimulation of hematopoiesis. An increase in circulating heterophil-leukocytes occurred within 24 hours with doses up to and beyond LD 50/30 days of total body irradiation, an observation previously reported by other investigators. The authors attribute this to a reaction to injury mediated through a mobilization rather than to the formation of new blood cells.

The changes noted on histologic examination were the same regardless of the type of irradiation used.

The spleens in the mice exposed to large amounts of beta rays in the focal irradiation experiments showed zones of radiation damage merging gradually with normal spleen. There was no zone of hyperplasia of undamaged cells at the periphery of the zone of radiation damage. Since beta rays have a limited range of penetration the authors point out that near the periphery of the range the small amount of radiation would evoke a stimulation. If such an effect occurred.

In the authors' experience external and internal ionizing radiation failed to produce evidence of primary stimulation in the blood-forming tissues and peripheral blood.

PAUL R. NOBLE, MD

The Value of Platelet Counts in Radiotherapy W. M. COURT BROWN. *Brit J Radiol* 1948 21 221

The increasing use of wide field roentgen therapy necessitates a more reliable indicator of the constitutional effects resulting from extensive irradiation of the bone marrow.

Red and white cell counts have previously been used as indicators during treatment, but in spite of these controls some patients have suffered from a temporary or permanent marrow failure at a later date.

Noting that skin hemorrhages similar to thrombocytopenic purpura often appeared just before severe anemia in cases of wide field irradiation the author investigated the effect of radiation on the platelet count as an indicator.

It was found that wide field radiation produces a fall in the blood platelet level which may be paralleled by the white cell count, but not always so. In

many cases the white cell count after an initial fall shows a tendency to rise and this rise may be maintained in spite of the continuance of treatment, being most marked in the leucemias. With more restricted forms of radiation in which a high local dose was given over bone similar platelet count drops were observed.

Following irradiation platelet counts continue to fall for a variable period returning to normal within month if the level at cessation of treatment was above 100,000 platelets per cubic millimeter.

In a series of over 100 cases it has been found that with the use of 300,000 platelets per cubic millimeter as the low limit of normal and 100,000 platelets per cubic millimeter as the lower limit of safety constitutional effects from excessive irradiation of the hemopoietic system have been completely avoided, and that adequate dosage has been administered.

Wide-field irradiation is not given to any patient with an initial platelet count below 100,000 per cubic millimeter and treatment is terminated when this level is reached.

Although textbooks state a platelet level below 40,000 per cubic millimeter is usually associated with purpuric manifestations, levels of roentgen ray-induced thrombocytopenia of the order of 15,000 to 20,000 platelets per cubic millimeter have been observed without petechial hemorrhages. In those cases with petechiae the time interval over which the petechiae appeared was very much shorter than the time interval over which the platelet level remained critically depressed. Some other factor besides thrombocytopenia is postulated for the production of petechial hemorrhages and several theories are advanced. The possible effects of roentgen irradiation on the prothrombin level are now being investigated.

ALLAN K. BRIDY, M.D.

Complementary Postoperative Radiotherapy for Breast Cancer (Radioterapia post-operatoria complementare del cancro della mammella) GIACCARIO PERLASCA. *Tumori*, Milano, 1947 33: 212.

The value of postoperative roentgenotherapy has always been in doubt; therefore the author made a study of the results obtained in the patients undergoing surgery alone and compared them with those obtained in patients undergoing surgery followed by irradiation.

The patients with carcinoma of the breast were classified according to the method advocated by Steinthal. Those in the first stage had a small, isolated, movable tumor with no palpable glands and no metastases. Those in the second stage had a larger tumor with attachment to the skin and the pectoral muscle, palpable lymph glands and metastases to these glands (verified by microscopic examination). Those in the third stage presented clinical metastases with involvement of the supradavicular glands.

The percentage of cure of patients with breast tumors in the first stage after 3 or 4 years was the same, whether or not they had received postoperative radiotherapy.

For those in the second stage, nothing was more helpful than removal followed by radiotherapy to get rid of the residual neoplastic tissue. One must not forget that x ray therapy is local and there are times when diffusion has already taken place and any spread is not affected by roentgen therapy. This explains the fact why some people die of metastases although the local lesion has been destroyed.

For patients in the third stage the use of postoperative roentgen therapy is only palliative as it only decreases pain and prolongs life.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Vitamin C Requirement of Human Adults: Experimental Study of Vitamin C Deprivation in Man. R. A. PETERS, K. H. COWARD II A. KREUS L. W. MARSON and OTHERS. *Lancet* Lond. 1948 1 853.

There is no agreement on the requirement of vitamin C in man. All are rough estimates and range from 30 mgm or less to 75 mgm.

This paper attempts to assess the daily requirements in human volunteers. There were 19 men and 1 woman between the ages of 21 to 34 years. They lived a normal life without strenuous physical work. Scurvy developed in all on the deprivation diet after 35 weeks apparent by the numerous hemorrhagic follicles on the legs by the gum changes by the redness and lividness of the scars and by the reduced tendency of the recent scars of incision to heal. Other tests revealed no significant findings.

The response to 10 mgm doses of vitamin C daily followed a general pattern. Hemorrhages ceased within a month wound tissues healed within 2 months but the gums required from 10 to 14 weeks for complete healing. The concentration of vitamin C in the plasma and white blood cells showed a small but distinct rise after 101 days.

Judged by the criteria available a dose of 10 mgm. of vitamin C daily was sufficient to maintain the normal healing power of the skin up to 11 months. In the nonsupplemented group severe defects in wound healing occurred similar to those recorded in scorbutic guinea pigs. These defects were encountered only when and not before clinical signs of scurvy had appeared. STEPHEN A. ZIEMAN M.D.

Thrombin and Delayed Thrombin: Modifiers of the Coagulation Time (Le thrombine et la thrombine retard modificateurs du temps de coagulation). MICHEL DUCHAUX, GEORGES CRUT and MICHEL GODDART. *Press méd* 1948 57 317.

The parenteral use of thrombin appears to be at least as important as its local application. It increases greatly the hemostatic capacities of the patient. Intravenous injections of 75 units of thrombin mixed with glycochol which acts as a buffer substance are well tolerated; they decrease the coagulation time in direct ratio to its original state. This mixture is called medical thrombin. The addition of a 5 per cent solution of magnesium hypophosphate to the medical thrombin reinforces its efficacy and makes its action less rapid but more prolonged, the reaction is such as to justify the term 'delayed thrombin'.

The authors have used intravenous injections of thrombin to prepare a hemophilic patient for dental extractions. They observed the following facts.

1 Two hours after an injection of medical thrombin the coagulation time fell from 360 minutes to 20 minutes.

2 The coagulation time then rose slowly but did not reach its original state 24 hours after the injection.

3 It was possible to lower the coagulation time by giving daily injections.

4. By adding a 5 per cent solution of magnesium hypophosphate to the medical thrombin any danger of coagulation in the syringe was avoided and the risk of sending an embolus into the general circulation was eliminated.

5 This combination of drugs did not reach its maximal effect before 8 hours had elapsed since the injection.

6 With this delayed thrombin the average coagulation time was less than that obtained with 7 times more medical thrombin. These facts were confirmed by observations in 2 other patients whose coagulation time was 25 and 30 minutes respectively.

The authors have injected up to 300 units of medical thrombin in a day and believe that the intravenous administrations should be reserved for severe cases. In average cases 150 units may be given orally on the eve and on the morning of the intervention in more serious cases intramuscular injections may be used.

Medical thrombin which acts quickly should be regarded as an emergency therapeutic measure capable of arresting the hemorrhagic accidents of any subject whose blood coagulates poorly. Delayed thrombin seems to get quite near to the ideal treatment of hemophilia. It is not yet what insulin is to diabetes but judging from the results obtained it is well on the way to becoming just as efficient.

RICHARD KEMEL, M.D.

Pathologic Studies in Secondary Shock (Pathologisch-anatomische Untersuchungen über den Wundchock). LAURI KALAGA. *Acta Soc med Duodecim* 1947 24 30.

The author refers to the paucity of reports of histological studies in secondary shock. It is true that there have been extensive studies in animals subjected to experimental shock but these do not necessarily reflect the changes seen in human beings. The author was unable to find complete studies with careful histological analysis of any large series of patients who had succumbed to shock. With the casualties attending war and the large number of high speed traffic accidents, the author undertook such a study in a series of 9 patients who had died presumably of shock. These patients had died at varying periods, from 5.5 hours to 4 days, following the trauma. The autopsies were performed very soon after death and all of the parenchymatous organs, the hollow viscera, and the skin, subcutaneous tissue and muscles were subjected to careful gross and histologic scrutiny.

The Parathyroid: A Study Based in Part on 60 Postmortem Examinations with Presentation of a Case of Hyperfunctioning Adenoma HACK U STEPHENSON JR. WILLIAM L MCNAMARA, and BURRILL GOLDBERGER *Am J M Sc* 1948 215 381

All of our knowledge of the parathyroid is relatively recent, since that organ was first recognized as an independent structure in 1880 and since it was not until 1902 that the first case of parathyroid tumor was reported. In this article the authors review the history of the diseases of this important gland and discuss its embryology anatomy histology and pathological physiology. In connection with the histology material is presented from the studies of 60 postmortem specimens.

The hormone secreted by the parathyroid glands acts largely upon calcium and phosphorus metabolism, apparently regulating the level of calcium ions in the blood. Hyperfunction produces typical disturbances most notable in the bones. There is some disagreement as to the manner in which these changes are effected. Collip and others believe that the hormone acts specifically on bone causing proliferation of osteoclasts and in turn resorption of bone and possibly formation of giant cell tumors. Excessive quantities of calcium and phosphorus are freed from the skeleton and carried in the blood to the kidneys and intestine. The resulting hypercalcemia and increased urinary calcium and phosphorus are logical consequences but the diminution of the inorganic phosphorus content of the blood is not clearly understood. On the other hand Albright contends that excessive parathyroid hormone acts primarily on phosphate metabolism lowering the renal threshold for phosphorus and increasing thereby the amount excreted in the urine. There is a consequent decrease of phosphate ions in the serum resulting in unsaturation of the blood with calcium phosphate and leading ultimately to liberation of the calcium phosphate of the bones. Such a view not completely confirmed by all investigations would make the parathyroid influence on calcium metabolism and on bone secondary to its regulation of phosphorus metabolism.

The diseases of the parathyroid are classified as primary states secondary states and neoplasms. Of the primary states it may be said that diffuse hyperplasia with hyperfunction is very rare so too is atrophy of the gland with hypofunction. In secondary parathyroid disorders there may be hyperfunction of the gland as a compensatory reaction to those conditions in which chronic renal insufficiency exists, with phosphate retention and chronic acidosis. There may be similar secondary hyperparathyroidism in diseases which deplete the available body calcium such as rickets or multiple myeloma. Secondary hypofunction sometimes accompanied by tetany occurs following extensive thyroidectomies in which parathyroid tissue has been excised or injured. The third category of parathyroid disease—neoplasms—consists almost entirely of adenomas as truly malignant tumors are exceedingly rare. Up to January 1947 there had been 337 cases of adenoma reported.

Those tumors which consist of oxyphil cells do not produce hyperfunction.

The classical symptoms and findings of osteitis fibrosa cystica and the more elusive manifestations of less severe hyperfunction are discussed. Four case reports are included. One of these deals at some length with a case of hyperfunctioning adenoma, the other 3 are concerned with other parathyroid disorders.

BENJAMIN F LOUNSBURY M D

Myxoma, the Tumor of Primitive Mesenchyma ARTHUR PURDY SROUT *Ann Surg* 1948, 127 706

The author defines myxoma as a true neoplasm composed of stellate cells set in a loose mucoid stroma through which course very delicate reticulin fibers in various directions. It resembles primitive mesenchyme and there are no recognizable differentiated elements. Growth is progressive and is both expansive and infiltrative. The tumor does not metastasize and if it kills it is because of damage to vital structures through compression or erosion. The author has found that it occurs about equally in males and females and in all ages from birth to old age with greatest frequency in the fifth decade. Anatomically, it occurs most frequently in the heart but it is also found in the skin and soft parts bones and genitourinary system. The fingers are most frequently involved when it is found in the skin; the mandible and maxilla are the most frequent bone sites and most of the genitourinary cases present involvement of the bladder.

While the tumors are usually small a tumor weighing over 5 kgm. was removed from the retroperitoneal space.

Röntgen ray therapy has not proved to be successful and because of the infiltrative nature of these tumors limited excision of the apparent growth has resulted in recurrences.

DANIEL RUOK, M D

A Proposition Concerning the So-called Xanthomatous Type of Giant Cell Tumors (A proposito de la llamada variedad xantomatosa de los tumores gigantocelulares) F SCHAJOWITZ and S MONDOLFO *Rev ortop traumat B. Air.* 1947 17 34

Giant cell tumors according to Ewing, are divided into xanthomatous xanthomatous, telangiectatic, and those arising from cartilage. Evidence is produced in this article showing that the xanthomatous type of giant cell tumor is hyperplastic, belonging to the histiocytic bone granulomas. The authors consider the evolution of the tumor as follows:

For these reasons the tumor should be called xanthomatous histiocytic granuloma or xanthogranuloma.

It is not possible to differentiate these tumors by roentgenography they are however histologically distinct. Because of their granulomatous origin they are benign and their prognosis is good following conservative treatment which consists of curettement and filling the defect with bone chips. Postoperative radiotherapy is not necessary if curettement is thorough.

EXPERIMENTAL SURGERY

Renal Transplantation; Anastomosis with Non-metallic Prostheses (Transplantation rénale anastomosée par prothèse non métallique) JACQUET (Report *Presse méd.* 1949, 58 319).

In his experiments on dogs, Oudot found that the best way to preserve the kidney between its removal and grafting was to immerse its vessels only in serum at 5° C. and to place the organ on a wet compress in closed glass. He heparinized the donor to prevent coagulation and made the anastomosis to the external iliac vein armed with nonmetallic prosthetic tube. Cutaneous ureterostomy is impractical because the animal tears off everything it can reach and the zone of implantation soon ulcerates. It is therefore necessary to have recourse to ureteral reimplantation without vesical patching.

The factors which contribute to the success of renal transplantation include the choice of young material, the quality of the venous anastomosis (especially without torsion), reduction of the size of the external iliac artery by placing a catgut suture on it that is moderately tightened, fixation and position of the kidney in the iliac fossa without angulation of the vessels, heparinization, avoidance of pressure on the ureter, conservation of the longitudinal ureteral vessel, and avoidance of infection.

Oudot reports his results. In homogeneous grafts cutaneous ureterostomy is an easy operation, but the kidney stops functioning after 10 days, gradually the rate of urea and chloride decreases and histologic examination shows a suppurative necrosis which changes the aspect of the organ completely. Ascending infection is the cause of the changes. In ureterostomy the problem is complicated by the ureteral factor.

It is necessary to wait for about a month to learn whether the graft is functioning or not. Only after the 2 normal kidneys have been removed is it possible to know whether the operation has succeeded and a 3rd kidney is grafted at a time this means that the animal must be submitted to four operations. This makes it a difficult experiment which often ends with a uremic animal. If extreme care is not taken the kidney becomes infarcted and the lesions predominate in the medulla. On the other hand, there is often a calcareous deposit in the epithelial cells of the tubules. The only animal that Oudot followed up until its death had had a double graft of homogeneous kidneys with vesical patching. It survived only 22 days but the volume of urine remained high for 6 days with a good concentration of urea and chloride. Autopsy revealed anastomoses without thrombosis and hydronephrotic and slightly infarcted kidneys with obstructed ureters.

In allogeneous grafts results were excellent provided that the kidney was normal from the beginning. It seems that the grafted kidney resumes its function only in the presence of a normal kidney. Afterward the normal kidney can be removed in its turn and replaced on the iliac vessels. Oudot now has several animals which are living and in excellent condition on two transplanted kidneys.

- Diagnosis, Spinal extradural cyst, report of case 11th particular reference to possible add 33, method of study of uterine canal, 58, calcium, phosphorus, and phosphatase as aids in, of bone lesions, 77 early treatment and results thereof of injuries to colon and rectum, with 70 additional cases collective review 105 new biologic reaction for of pregnancy (Gall-Malmgren's reaction) 70 studies on histopathological, in biopsies of mucosa of corpus uteri 264 pneumoencephalographic, in presenile dementias, 40 mesothelial mediastinal cysts (pericardial cysts); differential, of shadow's continuous with anterior inferior mediastinum, 459 value of celioscopy in gynecologic, 456; aspects of penetrating wounds of abdomen; collective review 52; differential, of jaundice, 57 carcinoma of pancreas criteria for, 57; use of vaginal smear in gynecologic service, 570 possible significance of arterial visualization in of placenta previa, 578
- Diaphragm, Paralysis of, 58 variations of contour of general, of disease which it mimics, 505; basal pleural fluid accumulations resembling elevated, 504 congenital hernia of anatomic and surgical importance of left triangular ligament of liver 459
- Diaphragmatic hernia, Traumatic, 251
- Ophthalmology Peripheral and central disturbances of visual fields aspect of 21
- Dislocations, Operative therapy for slipped upper femoral epiphysis end-result study 83; mechanism of injury and distribution of 3,000 fractures and, caused by parachute jumping, 188 slipped femoral epiphysis, 186; anatomopathologic basis and treatment of be bilateral, of shoulder 504, bilateral, of shoulder 387; recurring, of shoulder 388 review of 180 cases of recurrent, of shoulder 380; recurrent, of shoulder 380, symposium on recurrent, of shoulder 380, note on recurrent, of shoulder joint, 390 bone block for recurrent, of shoulder 390 results of treatment of congenital, of hip in infancy 494, results of treatment of irreducible congenital, of hip by arthrodesis, 494, end-results of early treatment of congenital, of hip, with inquiry into factors that determine result, 404 follow-up study of early treatment of congenital, of hip, 495; management of compound, 592 Magnuson Stack procedure for recurrent, of shoulder 592
- Diverticulum, Of bladder contribution to diagnosis and treatment, 345; malignant disease of stomach simulating gastric, 348 pathogenesis and surgical treatment of esophageal, 50
- Drainage, Early treatment and results thereof of injuries to colon and rectum 11th 70 additional cases collective review, 65
- Dressings, Primary postoperative hemostatic prophylactic, in abdominal surgery 1504 skin grafts, 597
- Ductless glands, Parathyroid; study based (in part) on 60 postmortem examinations 11th presentation of case of hyperfunctioning adenoma, 509
- Ductus arteriosus, Syndrome of aberrant right subclavian artery with patent, 40
- Duodenum, Special roentgenographic aspect that may be assumed by primary carcinoma of first part of, 95 postbulbar ulcer of 20 ulcer of 57 radical congenital pancreaticoduodenectomy 26 technique for pancreaticoduodenal resection 470 perforated gastric and duodenal ulcers statistics on 95 observations, 564
- Dyschondroplasia, Low radiolucous or Aladeh's disease, 589
- Dysentery, Allergic cholecystopathy and secondary bacteriemia following 554
- Dysgonadomas, Clinical and pathologic survey of ovarian tumors treated at Radiumhemmet, 167
- Dysmetria, Prenatal, curettomy for 269
- Dystocia, Functional, following cesarean section through transverse incision of lower segment, 64
- E**AR, Permanent deafness due to gunfire 28 foreign body in eustachian tube report of case 128 exposures in surgery of labyrinthitis, 28, repair of drum of, in blast injuries, 290 facial paralysis in otology 290; management of wound behind, following mastoidectomy 320, fenestration operation; survey of 300 cases, 320; contribution to question of otitis media in infants, 44; surgery of otosclerosis, 443 fenestration operation 443 clinical phenomena of deafness in light of new and old tests of 553 tricolostoid tube pedicle for otoplasty, 590
- Echinoscolex, Calcified halo; diagnostic sign of hydatid cysts of liver and operative approach to large cysts of superior and posterior surfaces of liver 3
- Echinoscolex, Retrovesicoprostatic cysts (hydatid cysts of pelvis) 487
- Edema, Hard dorsal post-traumatic, of hand, 91; production of allergic gastric and duodenal, which predisposes

FACIAL. Treatment of paralysis of by tantalum wire suspension; preliminary report, 31 paralysis of in otology 330; revivification of implantation of fascial strips through masseter muscle for surgical correction of paralysis of report of 3 additional cases, 33, plastic surgical repair of paralysis of 445 Langer's lines and scars of, 354

Fallopian's tetralogy. Ilithero unrecognized tendency to development of dispersed pulmonary vascular obstruction in patients with congenital pulmonary stenosis, 347

Fascia. Revivification of implantation of strips of, through masseter muscle for surgical correction of facial paralysis report 13 additional cases, 31

Fat. Parenteral nutrition studies on tolerance of dogs to intravenous administration of emulsions of, 208 parenteral nutrition. Improved techniques for preparation of emulsions for intravenous nutrition, 208 parenteral nutrition studies on soybean phosphatides as emulsifiers for intravenous emulsions of 208 emulsification due to involving human eye, 330

Fibula. Fractures of fibula dor to, 393

Femur. Operative therapy for slipped upper epiphysis of end-result study 83 anatomical study of mechanics, pathology and healing of fracture of neck of proximal femur report, 84 slipped epiphysis of, 86 indications and results of surgical treatment of monocondylar fracture of and tibial plateau, 300 final results of osteosynthesis of fractures of neck of ad modum Sven Johansson study of years material, 303 cartilage bone-cup arthroplasty in ununited fractures of neck of, 30

Fertilization. Survey of 500 cases, 329 operation of, 443

Fertility in men, 330

Fertilization, In vitro, and cleavage of human ovarian eggs, 37

Fetus, Premature births, 65

Fibrosarcoma. Fibrosarcoma of pancreas, review of 4 cases, 4

Fibrosarcoma, Gastric myoma and, 46 ovarian, with sarcoma and hydrothorax, 373

Fibrosarcoma, Peritendinous, of dorsum of hand, 403

Fibula. Fibula fractures of 303

Fleas. Aspects of penetrating wounds of abdomen collective review 52

Fistula. Problem of maintaining continuity of artery in surgery of aneurysms and arteriovenous, 203 employment of prone position in treatment of vesicovaginal, 360 congenital esophageal atresia and tracheoesophageal, 455 new method of restoring continuity of alimentary canal in cases of congenital atresia of esophagus with tracheoesophageal, not treated by immediate primary anastomosis, 456 constriction of skin-tube esophagus following surgical treatment of tracheoesophageal, 456

Flatfoot, Hypermobile, with short tendo achillis, 80 pes planus or instability of longitudinal arch, 39

Fluid, Control of body water balance, 308

Foot, Hypermobile flatfoot with short tendo achillis, for anatomy of, and examination for its disorders, 93; pes planus or instability of longitudinal arch, 39 functional pathology of experimental lameness, 308 tuberculosis of cuboid, 386 early operative treatment of fractures of tarsal scaphoid, 496 surgical treatment of intractable plantar warts, 304

Foreign body In ear-tachian tube report 1 case, 28 late reactions to metallic, 413

Fractures, Cystlike lesions of carpal bones associated with aseptic necrosis, traumatic arthritis, and ununited, 70, 1 tarsal contact splint, 85 anatomical study of mechanics, pathology and healing of femoral neck

preliminary report, 84, experimental study of sites of internal contact splint, 88 mechanism of injury and distribution of 3,000, and dislocations caused by parachute jumping, 85 indications and results of surgical treatment of monocondylar of femur and tibial plateau, 300, indications and technique in treatment of of humerus with paralysis of radial nerve, 395 final results of osteosynthesis of, of femoral neck ad modum Sven Johansson study of 10 years' material, 303 contribution to biochemical study of bone and callus in, 387 cartilage bone-cup arthroplasty in ununited, of neck of femur 301, pathological anatomy and treatment of, of lateral condyle of tibia, 39 treatment of, of malunion experimental study 393; of lower end of humerus in children, 493, early operative treatment of of tarsal scaphoid, 496 marrow-banking of recent pseudarthrosis and bone plastic, 496, primary closure of wounds of compound, with immediate internal fixation, immediate skin graft and compression dressings, 39 1 mechanism of, of carpal scaphoid, 302 fatigue, of fibula, 393 segmental arterial spasm associated with supracondylar of elbow report of case, 395

Freezing. Experimental and clinical studies of reduced temperatures in injury and repair in skin structure and potentialities of human skin in temperature control and in defense against thermal trauma, 0

GALL bladder. Cholecystectomy without drainage, 31 study of in obstructive jaundice by means of diagnostic pneumoperitoneum, 90 contributions to knowledge of pancreatic reflux as etiologic factor in chronic affections of experimental study 16 carcinoma of 164 cholecytic syndrome and lymph gland calcification of biliary liver 354, allergic cholecystopathy and secondary cholecystitis following dysentery 354 contribution to anatomohistologic study of benign tumors of 354 cuts, 456 surgical treatment of acute cholecystitis, 469 gas gangrene of 468

Gammagrays. Comparison of lethal effect of acronium and on mouse tumors () by irradiation of grafted tumors in vivo, (b) by irradiation of tumor fragments in vitro, 305

Ganglion. Surgical physiology of sympathetic nervous system with reference to cardiovascular disorders; collective review 417

Gangrene, Acute condition of abdomen following, of wall of cecum, 39, spontaneous, of acronium, 74, gas, of gall bladder 468 day, of newly born, 48

Garfield, President James A., Aspects of penetrating wounds of abdomen collective review 5

Gases, Effect of intestinal, upon balloons of intestinal decompression tubes, 37

Gastrostomy. Thirty-nine cases of total, 57 measured radical, 255

Gastritis, Observations on etiology of postoperative 46

Gastroenterostomy. End results in treatment of peptic ulcer by posterior 56

Gastrointestinal tract, Technical improvement in introduction of thread guide and its recovery with electromagnet in gastrostomy for cicatricial stenosis of esophagus, 44 surgical treatment of cardia, 44 tension-lateral antileptic gastrojejunostomy in gastric resection, 45 delayed results of surgical treatment of duodenal and gastric ulcer 47 47 production of allergic gastric and duodenal edema high predisposes to histamine-provoked ulcer in dogs, 153 pathophysiology of peptic ulcer clinical study 1 3 cases treated with ergotamine, 153 bleeding peptic ulcer 54 treatment of peptic ulcer 55 vagotomy for peptic ulcer, 56 experiences with vagotomy for peptic ulcer 56 opera-

- live treatment of chronic gastric and duodenal ulcer
 157 closure of colostomies, 159 gastroduodenal ulcer
 a peptic ulcer in aged, 255 vagus nerve resections, 253

Franchot Functional pathology of experimental lumen stenosis, 508
Tuberculosis Decortication of lung in treatment of empyema due to, 40 cervical adenitis due to, 129 fusion operation for bone and joint, associated with multiple foci, 187 clearing intestinal, and regional enteritis, 57 clinical-statistical contribution to study of 1 male genitalia, 270 meningitis and peroperational meningitis due to, 73 cancer and, in kidney 283 of colon, 286 results of peritubercular arthrodesis of knee 12, by Pott's method, 587, hysterolymphograms in genital, in women 400 further experiences in roentgen diagnosis of salpingitis due to, 400 surgical experience in 5 cases of gonitoidoendometrial, 476 tracheobronchial, 500, of appendix, 500 characterization in hysterolymphogram in salpingitis and endometritis due to, 574 renal, 582 adenocarcinoma and, of same kidney 584
Tubercula Uteroglandula treated with streptomycin, 595
Tumors Relationship between stage of development of, and age in determining prognosis of breast cancer, 38 contribution to study of primitive papillary, of renal pelvis, 68 scirrhous, of bladder so-called analbe 7 cases occurring in France 70 case of glioma, with primary involvement of bone, 00 contribution to study of salivary neoplasms, 133 carcoid body 3 juxta-adrenal paraganglioma (pheochromocytoma) with hypertension, operated on successfully disturbances of glyceregulation in paroxysmal hypertension 38 glandular bronchial epitheliomas (bronchial adenomas) 145, clinical and pathologic survey of ovarian treated at Radiumhemmet dysgerminomas, 167, malignant of testis treatment at Radiumhemmet, Blockholm, 70 conservative surgery in, of bone with special reference to segmental resection, 87 role of roentgenologist in diagnosis of polypoid disease of colon, 203, hilar densities stimulating neoplasms, 00 comparison of lethal effect of neutrons and gamma rays on mouse (a) by irradiation of gastro, in vivo, (b) by irradiation of fragments of in vitro, 205, cytogenetics and genesis of 200 mesenchymoma the mixed, 1 mesenchymal derivatives, 200, pathology of mucous and salivary gland, in lacrimal gland and relation to extra-orbital mucosa and salivary gland, 200, clinical significance of solitary nodule in thyroid gland 233 malignant, in aberrant lateral thyroid, 34 notes on pathology of cranial origination of in marrow of diploe 230 management of breast analysis of 356 cases, 645, thecoma xanthomatoid theocellular fibroma of ovary of Loeffler and Priesel mesenchymoma of ovary of Novak, 266 malignant, of ovary, 267 importance of accurate pathologic classification in prognosis of renal, 26 mixed, of kidney 8 metastatic, of ureter 283 of testis, 287 myeloplasmoma with malignant transformation, 3 malignant, of thyroid gland, 33 examination of spectrum for cells of 340 contribution to anatomohistologic study of benign, of gall bladder 354 primary double of ovary 357 sexuality function

ling ovarian, 357 clear-celled, of kidney, 367 proliferative of ureter 370 multiple vesical, characteristic of hypernephroma, 371 on pathology, and roentgen diagnosis of pical cancers and malignant peritapical, 204 plasma cell, 215 gelatin sponge in obliteration of cavities resulting from excision of cysts and, of liver, 444 primary vascular of pericardium, 454, Meigs' syndrome, 478 2 cases, of, of ureters discussion of surgical treatment, 486 serious limitations and erroneous indications of biopsy in diagnosis of, of bone, 496, primary of small intestine, 5 lymphoid, 5 3 intraluminal extension of sellar and parasellar neoplasms, 553 pinealoma, 556 diploic epidermoid and extradural porencephalic cranial defects and deformity 557 plain radiography of skull in diagnosis of intracranial, 600 proposition concerning so-called xanthomatous type of giant cell, 609

ULCER Results obtained by total conjunctival hooding of cornea, for keratomas, 20 statistical study of cases of benign gastric, 25 delayed results following surgical treatment of duodenal and gastric, 47 evaluation of the clinical management of chronic colitis with, 47 surgical treatment of colitis with, 48 surgical treatment of chronic colitis with, 15 primary resection of colon and rectum with reference to cancer and colitis, 5, production of allergic gastric and duodenal edema which predisposes to histamine-provoked, in dogs, 531 pathophysiology of peptic clinical study of 5 cases treated with ergotamine, 55 primary necropsic, of small intestine, 54 bleeding peptic, 54 treatment of peptic, 551 vagotomy for peptic, 56 experiences with vagotomy for peptic, 56 operative treatment of chronic gastric and duodenal, 157 gastric secretion after subtotal gastrectomy for study comparing reduction of secretion after gastrectomy and after vagotomy 158 Intestinal, due to arterial necrosis (malignant hypertension and polyarteritis nodosa) 58 postbulbar of duodenal, 20 gastro-duodenal a specific disease 253, vagus nerve resection, 233 peptic, in aged, 55 end-results in treatment of peptic, by posterior gastroenterotomy 56 late results following perforated peptic, 256 duodenal, 257 roentgenographic studies of gastrointestinal tract following section of vagus nerves for peptic, 245, treatment for gastric, 246 peptic, 246 peptic, following gastric resection, 247 further observations on treatment of bleeding peptic, 248 studies relating to perforated gastric and duodenal statistics on 95 observations, 268

Ureter Uretroendometrial anastomosis, 69 papillomas of kidney pelvis and of 75 transvaginal anastomosis between, and rectum, 76 modern concepts of calculus of 177 case of primitive epithelioma of, 283 primary carcinoma of 283 metastatic tumors of, 283 physiology of intact human 368 reconstruction of, with bladder flap 368 management of surgically traumatized, 369 proliferative tumors of, 370 megareteropyloroenteric anastomosis with loop for exsension, 485 2 cases of tumors (1 discussion of surgical treatment, 486) urinary calculi, 486 implantation of, into recto-sigmoid in case of urethrovesicovaginal fistula, 576 ureterosigmoid anastomosis, 584

Urethra Detailed anatomy of paraurethral ducts in adult human female, 6 tumorlike scleroses in sebaceous connective tissues of in women following castration or menopause 6, treatment of rupture after previous healing of membranous, value of preoperative ascending and retrograde urethrography and of employment of in-laying rubber tubing in reconstruction of 705 mib-

- hapse of prostatic resection 375 construction of term inal, in hypospadias, 585
- Urethritis, Reiter's syndrome 75 Reiter's syndrome 491
- Urinary tract, Detailed anatomy of paraurethral ducts in adult human female 61 possibility of surgical treatment of anuria 67 ureterooduodenal anastomosis, 69, treatment of renal insufficiency 173 transvaginal ureterorectal anastomosis, 1 6 wartime injuries of 183 vesical dysfunction 244 physiology of intact human ureter 368 management of surgically traumatized ureter 369 Immediate prostatectomy for retention of urine 377 epithelial metaplasia, 381 Implantation of ureters into in case of urethrovesicovaginal fistula 576 ureterotomoid anastomosis 584 renal transplantation anastomosis with nonmetallic prosthesis, 610
- Urine, Significance of so-called reaction of decompression in chronic retention of 249 Immediate prostatectomy for retention of 377 cancer cells in 492.
- Urology Oxyel in 290
- Uterine tubes, Concerning salpingography 60 abdominal contusion and rupture of pyosalpinx into free peritoneal cavity 267 nodular 268 accidental intravascular injections of lipiodol during hysterosalpingography 356 further experiences in roentgen diagnosis of tuberculous salpingitis 406, double ectopic pregnancy in one of 479, characteristics in hysterosalpingograms in tuberculous salpingitis and endometritis 574 6 cases of primary carcinoma of 575
- Uterus, Method of study of canal of 58 contribution to study of cysts of 58 ectodermal inasion of myometrium, 59 atypical endometrial hyperplasia simulating adenocarcinoma, 59 ultimate results in irradiation treatment of cancer of cervix of 60, clinical and histopathologic study of lesions of cervix of during pregnancy 63 complicating factors in radium treatment of carcinoma of cervix of 97 results of treatment of carcinoma of cervix of in Radiologic Institute of Helsinki from 1937 to 1942, 97, experiences with radiotherapy in cancer of cervix and of corpus of at Radium Center in Odense 98 contribution to morphological study of ovary and endometrium in myofibromas of 166 use of multiple sources of radium within in treatment of endometrial cancer 166, treatment of cervical cancer 167 summary of results in radium treatment and distribution in radium treatment of carcinoma of cervix of 204 studies on histopathological diagnosis in biopsies of mucosa of corpus of 204 evaluation of results of carcinoma of cervix of treated by radical vaginal operation 205 hysterectomy 356 accidental intravascular injections of lipiodol during hysterosalpingography, 356 endometrios outside of 360 salpingography, 360 with vaginal metastasis, 365 chorioepithelioma of 360 studies of carcinoma of cervix in urban population 356, studies of mucosa of 474 hystereography as diagnostic aid in submucous myoma, 474 surgical treatment of rectal complications of radiotherapy surgery 477 cancer of possibilities of sympathetic methods, 574 ear early detection by simple screening methods, 574 ear coma of 574 additional data in technique of vaginal hysterectomy 574 characteristics in hysterosalpingograms in tuberculous salpingitis and endometritis, 574-
- WAR Early treatment and results thereof of injuries to colon and rectum, with 70 additional cases collective review 105 200 injuries of urinary tract, 183 reconstruction of opposition digits for mutilated hands, 191 wounds of rectum and anal sphincter 352 late reactions to metallic foreign bodies, 413 arterial anastomosis in wounds of extremities, 502 historical aspects of penetrating wounds of abdomen collective review 521
- Warts, Surgical treatment of intractable plantar 594
- Water, Control of body balance of, 508
- Wounds, Penetrating, of cerebral ventricles, 39 role of spleen in relation to cutaneous healing of 101 early treatment and results thereof of injuries to colon and rectum, with 70 additional cases collective review 105 200 cross-sectional view of injuries in ophthalmic practice in Elre, 124 observations upon patients with penetrating, involving cerebellum, 134 histologic revision of process of repair of kidney, resulting from partial nephrectomy, 175, wartime injuries of urinary tract, 183, arterial injuries, 194 local treatment of whole thickness burn surface, 197 experimental and clinical studies of reduced temperatures in and repair 200 gram-negative meningitis following head, 240 observations on early management of gunshot, of arteries 297 management of behind ear following mas tolectomy 339 war of rectum and anal sphincter 352 factors influencing healing of anorectal surgical, 405 arterial anastomosis in war of extremities, 502 roentgenological manifestations of intra-thoracic injury
- VAGECTOMY Experiences with, for peptic ulcer 156.
- Vagina, Prolapse of vault of following hysterectomy: new method of repair 268 repair of combined with vaginal hysterectomy 269 absence of 358 pruritus of rectum and etiology and treatment, 359 employment of proce
- position in treatment of vesicovaginal fistula 360 additional data in technique of hysterectomy through, 574.
- Vaginitis, Treatment of with penicillin vaginal suppositories, 269.
- Vagotomy for peptic ulcer 156
- Varicocele Surgical technique advocated by author, 491
- Varicostitis, Simplification of diagnosis of 194 disasters following operation of ligation and retrograde injection of 297
- Vasokymogram and vascular flow 400
- Vasospasm, Use of prolonged continuous spinal anesthesia to relieve and pain in patients with peripheral embolism, 505
- Veins, Restorative endoaneurysmorrhaphy by graft inlay of 86 simplification of diagnosis of varicose 194 experimental study of effect of ligation of pulmonary in dog 247, disasters following operation of ligation and retrograde injection of varicose 297 surgical management of clotting in 397
- Venography Clinical and roentgenologic evaluation of 199
- Vertebrae Lesions of bodies of 185 some cases of paraspinal defects in anterior portion of body of with remarks on pathogenesis of lesions in question, 186 morphologic variations in first sacral, in cases of lumbarization, 202 atlanto-occipital fusion, occiput terminale and occipital as related to basilar impression with neurological symptoms, 509
- Villard syndrome Significance of choledochus, 53
- Vitallium Use of plates of to maintain function following resection of mandible, 19
- Vitamins, Effects of deficiency of on thyroid function studied with radioactive iodine 26 vitamin C requirement of human adults experimental study of vitamin C deprivation in man, 607
- Vitreous, Transplantation of preliminary report, 21
- Volvulus, Obstruction due to of colon 47
- Valva High lymphadenectomy and sympathectomy in carcinoma of 61

Trachoma, Denig's operation for pannus due to, 55
 Transfusion New technique for replacement in treatment of hemolytic disease of newborn infant, 87 normal red-cell survival in men and women 399
 Trauma, Treatment of open and closed cranio-cerebral injuries, 39 hard dorsal edema of hand following, 9 ; experimental and clinical studies of reduced temperatures in injury and repair in man structure and potentialities of human skin in temperature control and in defense against thermal, 63 traumatic pseudo-hydronephrosis, 173 mechanism of delayed death following thermal, 56
 Frenchfoot, Functional pathology of experimental inner moon foot, 308
 Tuberculosis, Decortication of lung in treatment of empyema due to, 40 cervical dentitis due to, 130, fusion operation for bone and joint, associated with multiple foci, 87, coarctizing intestinal, and regional enteritis, 57 clinical-statistical contribution to study of, of female genitalia, 170 meningitis and puerperal state, meningitis due to, 75 cancer and, to kidney 483 of tuboid, 356 results of peritubercular arthrodesis of knee in by Putil method, 187, hysteromphlogograms in genital, in women, 466 further experiences in roentgen diagnosis of salpingitis due to, 466 surgical experience in 5 cases of genitoabdominal, 476 trephinocephalic, 560 f. ppepud, 569 characteristics in hysteromphlogograms in salpingitis and endometritis due to, 574, renal, 582 adenocarcinoma and, of same kidney 584
 Telamula, Uteroglandular treated with streptomycin, 593
 Tumors, Relationship between stage of development of and go in determining prognosis of breast cancer, 58 contribution to study of primitive papillary, of renal pelvis, 68 tumor, of bladder so-called aniline 7 cases occurring in France 70 case of glioma, 11b primary involvement of bone 60 contribution to study of salivary neoplasms, 13 carotid body 31 juxta-adrenal paraganglioma (pheochromocytoma) 11b hypertension, operated on successfully disturbances of phycoagulation in paroxysmal hypertension, 38 glandular bronchial epitheliomas (bronchial adenomas), 143, clinical and pathologic survey of ovarian treated at Radiumhemmet dysgerminomas, 671 malignant, of testis treatment at Radiumhemmet, Stockholm, 79 conservative surgery in, of bone with special reference to segmental resection, 87 role of roentgenologist in diagnosis of polypoid disease of colon 803 hilar densities stimulating neoplasms, 801 comparison of lethal effect of neutrons and gamma rays on mouse (a) by irradiation of grafted, in vitro, (b) by irradiation of fragments of in vitro, 805, estrogens and growth of 806 mesenchymoma the mixed, of mesenchymal derivatives, 806, pathology of mucous and salivary gland in lacrimal gland and relation to extra orbital mucosa and salivary gland, 30 clinical significance of solitary nodule in thyroid gland, 11 malignant, in breast lateral thyroid, 234, notes on pathology of cranial origin of, in marrow of diploe, 230, management of breast analysis of 336 cases, 243 thecoma, xanthomatoid theocellular fibroma of ovary of Loeffler and Priewel mesenchymoma of ovary of Novak, 866 malignant, of ovary, 367 importance of accurate pathologic classification in prognosis of renal, 48 mixed, of kidney 88 metastatic, of ureter 235 of testis, 287 myeloplasmoma with malignant transformation, 3 malignant, of thyroid gland, 332 examination of sputum for cells of 340 contribution to anatomohistologic study of benign, of gall bladder 354 primary double, of ovary 357 actually function-

ing ovarian 357 clear-celled, of kidney, 367 proliferative, of ureter 370 multiple vesical, characteristic of hypernephroma, 371 on pathology and roentgen diagnosis of apical cancers and malignant perisplenic, 404 plasma cell, 45 gelatin sponge in obliteration of cavities resulting from excision of cysts and, of jaw, 444 primary vascular of pericardium, 454, Mclure syndrome, 478 a cases, of of ureters discussion of surgical treatment, 486 serious limitations and erroneous indications of biopsy in diagnosis of of bone, 498 primary of small intestine, 53 lymphoid, 53 intraluminal extension of sellar and parasellar neoplasms, 553 pleurocystoma, 556 diploic epidermoid and extradural pneumocoele cranial defects and deformity 557 plain radiography of skull in diagnosis of intracranial, for proposition concerning so-called xanthomatous type of giant cell, 609

ULCER, Results obtained by total conjunctival hooding of cornea, for keratoplasty, 30 statistical study of 1 cases of benign gastric, 45 delayed results following surgical treatment of duodenal and gastric, 47 evaluation of the clinical management of chronic colitis with, 47 surgical treatment of colitis with, 48 surgical treatment of chronic colitis with, 13 primary resection of colon and rectum with reference to cancer and colitis, 133 production of allergic gastric and duodenal edema which predisposes to histamine-provoked, in dogs, 53 pathophysiology of peptic, clinical study of 15 cases treated with ergotamine, 53 primary nonspecific, of small intestine 154 bleeding peptic, 54 treatment of peptic, 155 vagotomy for peptic 56 experiences with vagotomy for peptic, 156 operative treatment of chronic gastric and duodenal, 57 gastric secretion after subtotal gastrectomy for study comparing reduction of secretion after gastrectomy and after vagotomy 158 intestinal, due to arterial necrosis (malignant hypertension and polyarteritis nodosa), 58 postbulbar of duodenum, 50 gastro-duodenal spastic disease 55 vagus nerve resections, 253 peptic, in aged, 255 end-results in treatment of peptic, by posterior gastroenterostomy 56 late results following perforated peptic, 56 duodenal, 257 roentgenographic studies of gastrointestinal tract following section of vagus nerves for peptic, 245, treatment for gastric, 346 peptic, 346 peptic, following gastric resection 347 further observations on treatment of bleeding peptic, 348 studies relating to perforated gastric and duodenal statistics on 95 beer victims, 568

Ureter Ureteroduodenal anastomosis, 64 papillomas of kidney pelvis and of 175 transvaginal anastomosis between and rectum, 176 modern concepts of calculus of 177 case of pyelitis epithelioma of 283 primary carcinoma of 213 metastatic tumors of 283 physiology of intact human, 368 reconstruction of 11b bladder flap, 368 management of surgically traumatized 369 proliferative tumors of 370 angioarterio-lytic ureteral anastomosis 11b loop for excision, 453 3 cases of tumors of discussion of surgical treatment, 486 urinary calculi, 486 implantation of into rectosigmoid in case of urethrovesicovaginal fistula, 376 ureteroileoid anastomosis, 584

Urethra, Detailed anatomy of paraurethral ducts in adult human female 6 tumorlike sclerosis in submucous connective tissues of in women following castration or menopause, 6, treatment of rupture after previous healing of membranous, value of preoperative ascending and retrograde urethrography and of employment of in-lying rubber tubing in reconstruction of, 70, air-
